

Figure 67.5 This classic graph shows characteristic postburn changes in cardiac output and peripheral vascular resistance in a group of seven patients (mean burn size 64.5% total body surface area [TBSA]) resuscitated with the Brooke formula (lactated Ringer's [LR] solution, 1.5 mL/kg/%TBSA, albumin, 0.5 mL/kg/%TBSA, plus 2000 mL dextrose/water in the first 24 hours). Cardiac output falls acutely, before blood volume has changed appreciably, then rebounds gradually, with return to normal by 24 to 36 hours, and thereafter remaining above normal. Peripheral vascular resistance shows an opposite effect. (From Pruitt BA Jr, Mason AD Jr, Moncrief JA: Hemodynamic changes in the early postburn patient: The influence of fluid administration and of a vasodilator (hydralazine). *J Trauma* 1971;11:36-46.)

resuscitation varies significantly among units. One example exists in defining the end points of resuscitation. Successful resuscitation requires meticulous monitoring and adjustment of resuscitation based on patient response. Traditional resuscitation relies almost exclusively on hourly urine output for this purpose, so the amount of fluid required for resuscitation depends partly on the urine output targeted. Baxter used an output of 50 to 70 mL/hour; several other formulas that accept outputs of 0.5 mL/kg/hour (1.0 mL/kg/hour in children) call for LR infusion rates between 2 and 3 mL/kg/%TBSA, and are also in widespread use.^{34,36}

THE PHENOMENON OF "FLUID CREEP"

Clinicians have long accepted the consensus that patients should receive as little fluid as possible to maintain organ perfusion.⁵⁸ But several patient groups routinely require more resuscitation fluid than predicted by the Parkland formula, including patients with inhalation injury,⁵⁹ those with multiple trauma and electrical burns, patients in whom resuscitation is substantially delayed,⁴ and patients with alcohol or drug abuse.⁶⁰ Inexperienced clinicians often make substantial errors in estimating burn size, which can result in significant under- or overestimation of fluid requirements.¹¹ Careful monitoring of resuscitation and individualized fluid therapy can often obviate these problems.

But in recent years a widespread tendency for patients to receive increasing quantities of resuscitation fluid has been observed, a phenomenon dubbed "fluid creep" by Pruitt.⁶¹

Cancio and associates found that 63% of their recent patients required a mean of 6.1 ± 0.22 mL/kg/%TBSA for resuscitation despite very modest urine output.⁶² Others have documented such increased fluid requirements in up to 100% of patients.⁶³⁻⁶⁵ The potential complications of fluid creep are far from benign, including extremity and abdominal compartment syndromes, worsening pulmonary dysfunction, and more frequent and prolonged endotracheal intubation. Figure 67.6 illustrates the actual resuscitation of a child who required an excessive amount of crystalloid to achieve successful resuscitation and maintain adequate urine output.

This departure from tradition is probably due to several influences. First, the successful resuscitation of patients with massive burns appears to routinely require increased fluid volumes.⁶² In Baxter's initial report of 277 patients, 89% of those with burns 60% TBSA or greater died.⁴⁵ However, modern survival is much better and owes some of its success to persisting with aggressive fluid resuscitation beyond the confines of the Parkland formula.

Second, it appears that fluid creep perpetuates itself. Overly zealous initial fluid administration—often performed in the field—increases serum protein depletion, generating a vicious circle of reduced oncotic pressure and enhanced edema, which in turn increases crystalloid requirements. This mechanism also helps explain the occurrence of resuscitation failure, in which fluid requirements actually escalate despite adequate—or excessive—crystalloid administration.⁶⁶ The use of colloid-containing fluids can arrest this cycle and restore oncotic pressure but adds to overall fluid requirements as well.

Fluid creep has probably also been encouraged by resuscitation trends in other ICU populations. Traditional burn resuscitation formulas permit significant deficits in vascular volume and cardiac output to persist until the end of 24 hours.⁴⁵ The routine observation of hematocrits as high as 70% during resuscitation is consistent with this concept. Both lactic acid (LA) and base deficit (BD) remain elevated throughout traditional resuscitation,⁶⁷ which also fails to reflect changes in cardiac output and oxygen delivery (VO_2).⁶⁸ In contrast, resuscitation in other shock states has been increasingly directed at normalizing LA and BD, and optimizing cardiac output, VO_2 , and pulmonary wedge pressure.^{69,70} As this concept gained acceptance in critical care, burn clinicians have become more inclined to monitor these parameters and to respond to abnormalities by increasing fluid support.

However, this approach may not be valid in burns. Although it is accepted that patients' ability to achieve optimal values of cardiac output and VO_2 correlates strongly with outcome, it is less clear whether exaggerated fluid infusion, invasive monitoring, and inotropic support can change nonresponders into responders and thus improve survival.⁷¹ Optimizing VO_2 and improved survival in one group of patients with severe burns,⁷² but both Kaups and colleagues⁶⁴ and Choi and coworkers⁶⁵ were unable to determine if resuscitation aimed at normalizing elevated BD was effective or beneficial. In other studies of goal-directed therapy in burns, attaining target values of cardiac output, VO_2 , or wedge pressure routinely required more fluid—as much as four times Parkland calculations—without obvious improvement in survival,^{73,74} and potential increase in edema-related

Figure 67.6 Time course of fluid resuscitation for a 6-year-old boy (20 kg) with 33% total body surface area (TBSA) scald burns. He arrived at the burn center 6 hours after injury, having received 900 mL of lactated Ringer's (LR) solution prior to arrival. Fluid resuscitation was started according to the Parkland formula (*heavy dashed line*); nurses were instructed to maintain urine output between 0.9 and 1.8 mL/kg/hour (*dotted line*). Initial resuscitation was close to Parkland guidelines, but beginning at about 10 hours after burn, fluid requirements increased progressively until about 22 hours, when urine output finally began to rise, and fluids were tapered in a stepwise manner according to protocol. The patient reached his calculated maintenance fluid rate of 106 mL/hour at hour 36. Total resuscitation received was 11.38 mL/kg/%TBSA. He had no difficulties with compartment syndromes or respiratory distress. This case illustrates the occurrence of "fluid creep" that has been experienced frequently in modern burn care.

complications, which appear directly related to the fluid volume administered.^{75,76}

It is clear that the optimal method of monitoring and delivering burn resuscitation has yet to be determined. Although fluid creep is widespread, most burn centers still base fluid administration primarily on urine output. Invasive hemodynamic monitoring does not appear beneficial for routine use, though it may be helpful in guiding therapy in individuals who are clearly failing to respond to traditional resuscitation, including elderly patients or those with massive injuries, cardiac disease, associated multiple trauma, or severe pulmonary dysfunction.

HYPERTONIC RESUSCITATION

Crystalloid solutions remain the mainstay of all resuscitation regimens as they are inexpensive, well tolerated, readily available, and easily mobilized and excreted. The effective component of crystalloid is sodium,⁷⁷ which has led to the use of hypertonic saline solutions to satisfy capillary and cellular leakage while minimizing fluid volume and edema.^{78,79} Solutions containing as much sodium as 300 mEq/L result in delivery of almost identical quantities of sodium as LR solution with substantially less volume.⁸⁰ Hypertonic saline resuscitation has been advocated for children⁸¹ and the elderly,⁸² who tolerate under- and overresuscitation poorly, as well as for patients with head injuries,⁸³ and for field and combat resuscitation when the weight of available solutions must be minimized.^{84,85}

Hypertonic saline resuscitation carries the risk of significant hyponatremia, hyperchloremia, acidosis, and hyperosmolarity, and requires careful monitoring. In addition, savings in initial fluid requirements may be balanced by increased free water retention later.⁸⁶ Hypertonic saline has been associated with increased mortality risk in at least one study, possibly related to increased renal failure.⁸⁶ However, it is still used selectively in some burn centers^{79,87} and remains an option in acute burn management.

CRYSTALLOID VERSUS COLLOID

Because of the indiscriminate nature of early postburn capillary leakage, colloids are not superior to crystalloids in initial burn resuscitation.⁵⁵ For this and other reasons, colloid use in resuscitation of all types has been condemned.⁸⁸ However, capillary integrity is largely restored by the end of 24 hours after injury, and colloids given at this time can effectively restore oncotic pressure, expand plasma volume, and reduce secondary edema in unburned tissue,^{35,51} including possible prevention of abdominal compartment syndrome.⁸⁹

Colloids used in burn resuscitation have included albumin, plasma protein fraction (Plasmanate), fresh frozen plasma, and the synthetic colloids dextran and hetastarch. Routine albumin administration is a component of the traditional Evans and Brooke formulas^{36,55} and was originally used at the end of Parkland resuscitation.³⁵ In a widely quoted randomized trial, Goodwin and associates

found that albumin-based resuscitation required less total fluid than solution alone but was associated with a sustained increase in extravascular lung water.⁹⁰ Critics have also pointed out that routine albumin supplementation has no apparent benefits.⁹¹ Nonetheless, albumin remains a popular colloid; its current use varies among burn centers from routine administration within 8 to 12 hours of injury,^{50,57} to selective use as “rescue” in problem resuscitations, to near-total interdiction. Fresh frozen plasma has also been used successfully⁹²; its colloid effect probably explains much of the efficacy of plasma exchange therapy in complex burn resuscitations.⁹³ Both low-molecular-weight dextran and hetastarch have been used in burn resuscitation and appear as effective as albumin in maintaining oncotic pressure and limiting edema in unburned tissues.^{51,94,95} They offer advantages of long shelf life, availability, freedom from disease transmission, and lower cost. However, hetastarch has been associated with rare anaphylaxis and dose-dependent coagulopathy and bleeding, which limits its use in large volumes.⁹⁶

Colloid is probably unnecessary for resuscitation of most patients with uncomplicated injuries. With increasing burn size, the benefits of colloid administration, restricted to use after the first 8 to 12 hours after burn, may be significant in reducing total fluid requirements and edema-related complications. Many centers now utilize LR solution for the first hours after injury, followed by hypertonic saline, colloid, or both to reduce edema as resuscitation is completed.⁵⁷ The patient illustrated in [Figure 67.6](#) would be a very appropriate candidate for this form of “rescue” therapy, which would likely have reduced his ongoing fluid requirements. This area of resuscitation is extremely controversial and will benefit from randomized multicenter trials.

PHARMACOLOGIC MANIPULATION OF RESUSCITATION

Improved understanding of the pathophysiology of burn shock has led investigators to attempt to reduce its severity by blocking some of its specific chemical mediators. These efforts have included use of vasodilators such as hydralazine, histamine blockade using cimetidine, the serotonin antagonist ketanserin, and anti-inflammatory drugs such as hydrocortisone and ibuprofen.^{43,55,97-99} Large doses of the antioxidant vitamin C has been shown to decrease fluid requirements in clinical burn resuscitation.¹⁰⁰ Many of these efforts have shown modest benefits, though none has found its way into widespread clinical use. The possibility of developing an effective “cocktail” to ameliorate the effects of burn shock holds promise for the future.

PRACTICING EFFECTIVE RESUSCITATION

A bewildering array of regimens (and opinions) are in current use for burn resuscitation. In attempting to practice resuscitation effectively, the clinician must decide on a protocol that is uniform and easy to apply by nurses, yet flexible enough to permit individualized therapy and provide appropriate “escapes” for patients who are unstable.

An example of the protocol used at the University of Utah is included in [Figure 67.7](#). The protocol is based on the Parkland formula, but contains an option for the use of LR/albumin to arrest escalating fluid requirements. It requires nurses to adjust infusions based on hourly urine output, but

mandates that physicians be contacted if worrisome parameters develop. We have found this protocol effective in resuscitating the vast majority of patients without frequent input from physicians. Similar protocols are in use in a number of burn centers.

COMPLICATIONS OF EDEMA

Although the quantity of edema in both burned and unburned tissue is affected by fluid resuscitation, it is also true that substantial swelling occurs regardless of the resuscitation used. Swelling within the face, eyes, extremities, and torso can have catastrophic consequences if untreated, and it is essential to remember that edema is progressive for 24 hours following burn injury; an area that is soft and pliable on admission may become tensely swollen within hours or overnight. Clinicians must be aware of the potential for these complications, follow serial examinations, and treat them as they develop.

FACIAL SWELLING

Full-thickness facial burns can swell massively and produce complete airway obstruction within an hour or 2 of injury, as illustrated in [Figure 67.2](#). As discussed under initial assessment, endotracheal intubation is essential in this setting and should be performed early and electively.

Continued facial swelling may preclude safe extubation for several days following injury, and inadvertent extubation in this period can be disastrous. Tubes must be secured carefully; patients may require sedation or paralysis to ensure this. As edema begins to resolve within 48 to 72 hours, extubation should not be attempted until patients can open their eyes and breathe spontaneously and an air leak can be demonstrated with the cuff deflated. Early tracheostomy may provide a more comfortable and secure airway for patients with large injuries.

OCULAR SWELLING

Elevated intraocular pressures (IOPs) have been documented in burn patients and appear to correlate with resuscitation volume. No data exist on the consequences of this phenomenon, but the risk of optic nerve ischemia and permanent visual loss may exist. Lateral canthotomy has been recommended for patients with persistently high IOPs.^{101,102} Measurement of IOP during acute burn resuscitation may be warranted in patients with severe facial injuries and eyelid edema.

EXTREMITY COMPARTMENT SYNDROMES

Burns probably constitute the most common cause of extremity compartment syndromes. The pathophysiology is identical to that which accompanies fractures, crush injuries, and so on with the notable exception that in burn patients the constricting layer is the burn eschar, not the underlying fascia, so that incision through the burn wound—“escharotomy”—is required to relieve compression.

Failure to diagnose circulatory embarrassment of a burned extremity can lead to progressive ischemia, myonecrosis, and amputation. Because this can develop insidiously in burned extremities that are soft on presentation, a high index of suspicion and performance of serial examinations are essential. Compartmental compression is most likely

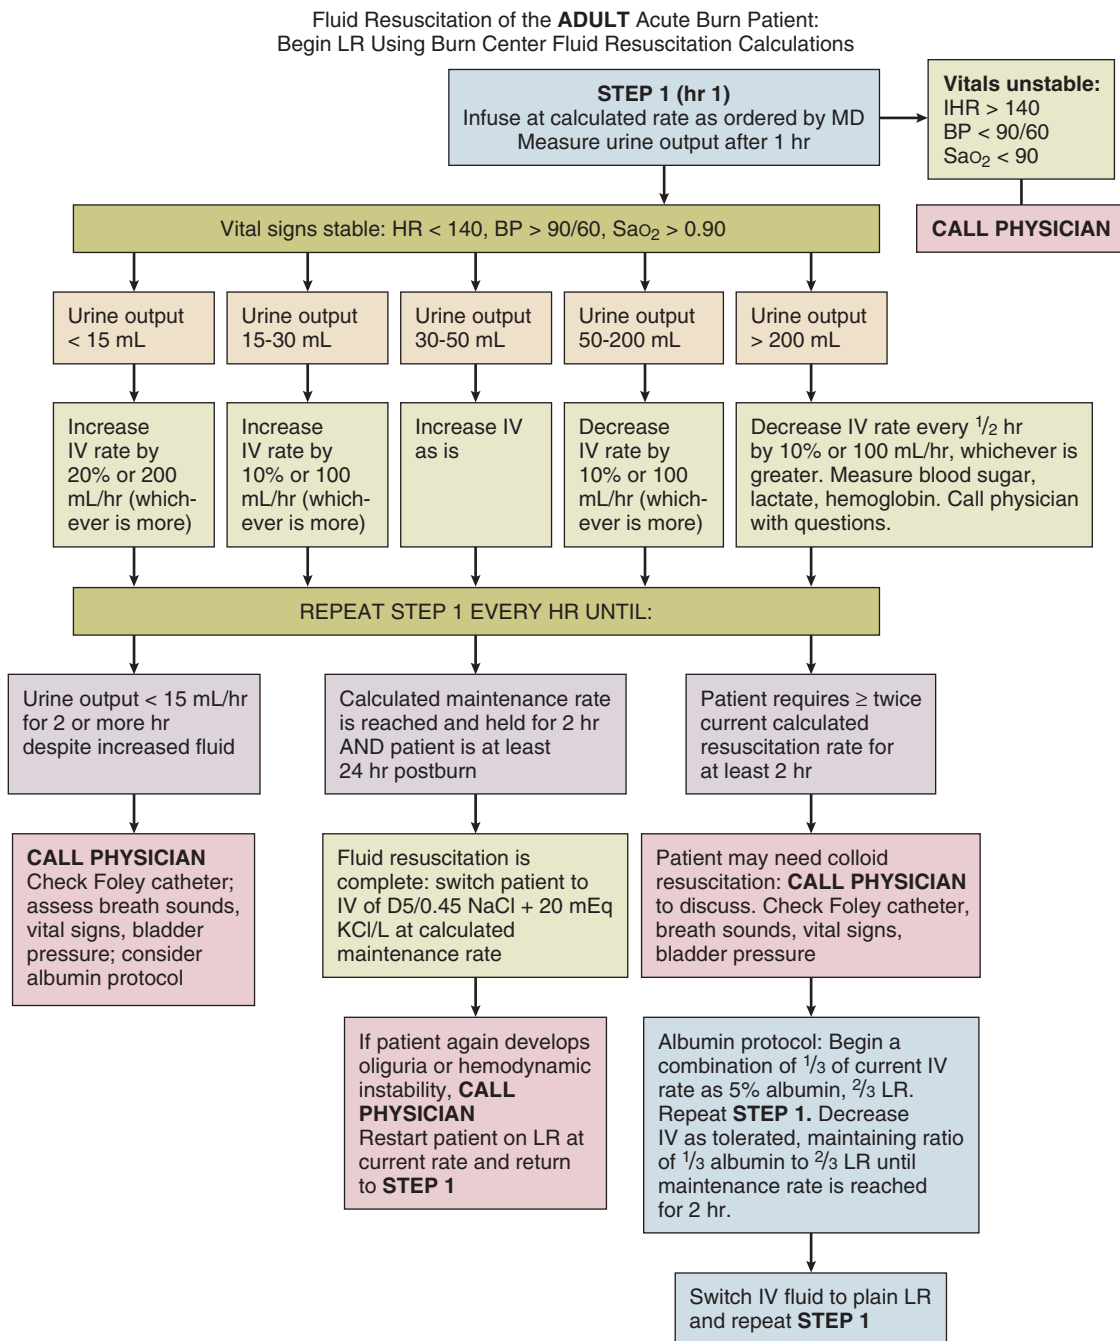

Figure 67.7 Burn fluid resuscitation protocol used at the University of Utah. Physicians order an initial infusion rate of lactated Ringer's solution based on Parkland calculations, and indicate the target maintenance rate. Nursing staff measures hourly urine output, and increases or decreases fluids based on this response. If patients develop unexpected changes in vital signs, or fail to respond appropriately, physicians are contacted. An option for the use of colloid-containing resuscitation is included for patients whose requirements fail to decline. This regimen permits close titration of fluids without requiring hourly physician input.

following full-thickness, circumferential extremity burns but can develop in the absence of these findings, even in unburned extremities in patients who require excessive resuscitation volumes, particularly children.

Swollen extremities should be initially treated with elevation and avoidance of constricting dressings. Classic findings of pain, paralysis, pallor, paresthesia, pulselessness (the “five Ps”) may be difficult beneath burn injuries or in intubated patients, and may not develop until irreversible

ischemia has occurred. Similarly, limb-threatening compression can exist despite persistent palpable or Doppler pulses.¹⁰³ For these reasons, some authorities perform escharotomies based on a general impression of extremity swelling, or even prophylactically. Alternatively, many clinicians monitor intramuscular pressure to determine the need for decompression. This procedure is easily done by inserting a large-bore (18-gauge) needle attached to a pressure transducer through the eschar into the underlying muscle.

Figure 67.8 Massively swollen forearm following high-voltage electrocution injury. Simple escharotomy of the distal forearm and hand failed to decompress the extremity, so extensive fasciotomy was performed to above the elbow. The skin edges are widely separated by edema. Proximal forearm muscles are viable, but tissues distal to the drawn line—the line of anticipated amputation—are clearly necrotic. The wrist and fingers are “frozen” in flexion caused by contraction of damaged muscles.

Pressures that exceed 30 cm H₂O in the relaxed extremity indicate compromised capillary perfusion and mandate decompression.¹⁰⁴ Measurements should be repeated following escharotomy; pressures that remain elevated indicate the need to deepen or extend incisions or to proceed with fasciotomy. This may be particularly likely in patients with very deep burns, associated trauma, or electrical injury (Fig. 67.8).

Escharotomies can often be done at the bedside using electrocautery and appropriate analgesia. Longitudinal incisions should run the length of the burn wound, be placed medially and laterally on the supinated limb to avoid major nerves and vessels, and facilitate resurfacing with skin grafts. Incisions must penetrate through the burn until the wound edges “pop open,” and pressure is clearly relieved. Incisions in burned hands should extend at least to the metacarpophalangeal joints; performance of individual digit escharotomies has some support¹⁰⁵ but is often omitted. As an alternative, the use of enzymatic debriding agents to provide chemical escharotomy is popular in some centers.¹⁰⁶

TORSO COMPARTMENT SYNDROMES

Recent awareness of massive abdominal swelling as a cause of cardiorespiratory compromise has led to protocols for monitoring intra-abdominal pressure and performing decompressive laparotomy in many ICU populations. In burn patients, occurrence of abdominal compartment syndrome has accompanied reports of fluid creep, as discussed earlier,⁷⁵ though it can clearly develop in the absence of excessive resuscitation. Patients with major ($\geq 25\%$ TBSA) burns and extensive torso injuries or who require large resuscitation volumes (≥ 500 mL/hour⁷⁶) should have routine monitoring of bladder pressures.^{76,107} The finding of intra-abdominal hypertension in the absence of clinical symptoms should prompt other measures to reduce abdominal pressure.¹⁰⁸ There is evidence that both hypertonic saline and colloid-based resuscitation can prevent the development of abdominal compartment

Figure 67.9 Complications of edema in an elderly man with 70% total body surface area burns. Facial edema is massive; tracheostomy has been performed to provide secure, long-term airway support. Escharotomies on upper extremities and multiple torso escharotomies have resulted in increased swelling and separation of wound edges. Despite these measures, abdominal compartment syndrome necessitated bedside laparotomy and placement of a synthetic mesh “silo” to contain eviscerated abdominal contents. As edema resolved over several days, viscera were gradually returned to the abdomen and the silo was trimmed, until closure of the fascia was possible. The other escharotomy wounds were covered with skin grafts.

syndrome^{79,89}; removal of peritoneal fluid with dialysis catheters has also been effective.¹⁰⁹ Unfortunately, many patients with abdominal compartment syndrome present with diffuse retroperitoneal swelling rather than free peritoneal fluid; diagnostic ultrasound can make this decision and guide catheter placement if free fluid is seen.

Like other edema-related complications, abdominal hypertension can develop insidiously and then present precipitously with oliguria and critical hypotension and respiratory embarrassment. In patients with deep burns of the chest or abdomen, performance of torso escharotomy—sometimes repeatedly—will often improve ventilation and obviate laparotomy. Patients in whom other measures fail or symptoms progress rapidly should undergo immediate decompressive laparotomy, at the bedside if necessary. Delayed decompression may worsen shock and even lead to intestinal necrosis, although prompt decompression will both improve survival and reduce ongoing resuscitation requirements.¹¹⁰ Containment of the exposed viscera by mesh or plastic silos may be needed following laparotomy, as widely used “vac-pack” dressings¹¹¹ may be impossible to secure over burn eschar. As edema resolves, every effort should be made to reduce abdominal contents and obtain fascial closure through repeated wound revisions. [Figure 67.9](#) illustrates a patient in whom numerous complications of edema—massive facial swelling, extremity compartment syndromes, and abdominal compartment syndrome—have occurred simultaneously. Although the mortality rate of abdominal compartment syndrome in burn patients is high,¹¹² this likely reflects the severity of the underlying burn more than this complication itself.

ACUTE RENAL FAILURE

The development of effective protocols for fluid resuscitation has greatly reduced the incidence of acute renal failure (ARF) during initial burn treatment. ARF may still develop if resuscitation is delayed or inadequate,¹¹³ particularly in patients with high-voltage electrical injuries or extremely deep burns, in whom pigment-induced nephropathy from myoglobin/hemoglobin is possible. Patients with visibly red or black urine should have resuscitation increased to produce urine outputs of 50 to 100 mL/hour. A one-time initial dose of an osmotic diuretic such as mannitol to stimulate urine production, and alkalization of the urine by adding bicarbonate to intravenous fluids, is also widely practiced.^{114,115}

ARF in burn patients is now most often a late complication of infection or dehydration and continues to have a high mortality rate.¹¹⁶ Clearly its prevention is the best management strategy through meticulous fluid management and infection control. When ARF develops, patients should be treated with dialysis according to standard indications. Continuous renal replacement therapy can be particularly effective in managing patients who tolerate intermittent dialysis poorly.¹¹⁷ Nutritional support should not be reduced in this setting; rather, patients should continue to receive the calories and protein they require and undergo dialysis as needed.

ELECTROLYTE ABNORMALITIES

Although almost any disturbance of electrolytes can occur during the course of an acute burn, several characteristic patterns are seen. Most frequent are disturbances in serum sodium concentration. Massive resuscitation with LR solution (sodium content 130 mEq/L) results in the infusion of a large sodium load. Following resuscitation, urine output will be less reflective of intravascular volume, and serum sodium concentration will reflect free water balance. The formula given previously for maintenance fluids following resuscitation provides only a rough estimate of individual requirements, which can also be affected by fever, ventilator support, hyperglycemia, and other abnormalities. Progressive hyponatremia should prompt a reduction in total free water intake, although hypernatremia should be treated with increased free water. Dehydration can develop insidiously despite adequate daily urine output.

Hypokalemia may occur immediately after burn related to epinephrine release from injury,¹¹⁸ although hyperkalemia can result from cellular injury and acidosis. Both are usually short-lived and rarely require treatment. Thereafter, potassium levels often drop below normal, and patients may require substantial supplementation. Elevated aldosterone secretion following burn injury contributes to chronic hypokalemia and alkalosis.¹¹⁹ Magnesium levels also commonly drop, and supplementation of both potassium and magnesium is required as part of the “refeeding” effect of aggressive nutritional support.

Hypophosphatemia is also extremely common from multiple causes including catecholamine secretion, metabolic alkalosis, impaired renal phosphate absorption, and increased excretion during postresuscitation diuresis.¹²⁰ Phosphate levels typically reach a nadir 2 to 5 days after injury, and afterward rebound slowly. Significant

hypophosphatemia can lead to cardiac dysfunction, reduced red blood cell survival, and neurologic abnormalities, particularly during refeeding. Substantial phosphate supplementation may be needed throughout the wound coverage phase of burn treatment. Routine monitoring and replacement of all electrolytes should be performed at least until patients no longer require intravenous fluids.

THE WOUND COVERAGE PHASE

SURGICAL TREATMENT OF BURN PATIENTS

Although effective fluid resuscitation has reduced the acute mortality risk of burned patients, aggressive surgery has produced the greatest advancement in overall survival from burns. Early excision of wounds and coverage with skin or skin substitutes work to remove burn eschar as a major source of infection, shorten the period of severe hypermetabolism, relieve pain, improve function, and permit earlier mobilization and preservation of muscle mass.

Burn eschar left in place eventually separates from underlying tissue through the action of leukocyte enzymes. Bacterial infection facilitates this process, and burn eschar is an ideal medium for bacterial growth. In the era before routine excision, many patients died from sepsis while awaiting eschar separation while experiencing unremitting pain and prolonged muscle wasting. Surgical excision of burns was first practiced in the early twentieth century but produced high mortality rates from blood loss and anesthesia. Beginning in the 1970s, improved support has permitted aggressive excision of major burns with increased survival and decreased length of stay.^{121,122-124} Early excision is now considered a standard of care. A detailed discussion of these techniques is beyond the scope of this chapter. However, intensivists must be aware of the principles of surgical treatment and be able to support patients pre- and postoperatively.¹²⁵

INDICATIONS AND TIMING OF SURGERY

The larger the burn injury, the more acute the need for early excision. Patients with small (<10-15% TBSA) burns can be followed for up to 14 days to evaluate healing, but when burn size exceeds 25% to 30% TBSA, a widely accepted goal is removal of essentially all of the burn wound within 7 days of injury. Muller and Herndon excise the entire wound in a single procedure even while fluid resuscitation is ongoing,¹²⁶ but most units practice a staged approach, removing 15% to 20% TBSA at each operation.

En bloc excision of skin and subcutaneous tissue to vascularized fascia is rapid and relatively bloodless and creates a reliable bed for skin grafting. It is often practiced in the elderly and for particularly deep burns. However, fascial excisions are disfiguring and cause substantial problems with joint stiffness and pain. Far more common today is “tangential excision,” in which thin slices of tissue are removed until a viable bed of dermis or subcutaneous fat is reached. This requires more skill and time and produces more blood loss, but long-term results are unquestionably superior.

Unless covered, excised wounds will desiccate and develop a new layer of necrotic tissue—in essence, a second

eschar—with attendant metabolic stress, pain, and infection. The ultimate goal of excision is autografting—coverage with the patient's own skin. Burns excised within 7 to 10 days of injury are usually quite clean, and are often autografted immediately, providing prompt wound closure and facilitating early mobility. If donor sites are limited, autografts can be meshed to expand and cover more area. Excised wounds can be covered with antibiotic-soaked dressings to maintain tissue viability and combat infection for a few days. In recent years, a variety of skin substitutes have been utilized when donors are not available or if burns appear infected or poorly vascularized. The most widely used material is cadaver allograft skin obtained from tissue banks. Like autograft, allograft permits vascular ingrowth and take—sometimes for weeks—though this tissue is always eventually rejected. Allograft placement reduces bacterial colonization and pain, retards wound contraction, creates a clean, vascular bed, and can serve as a test for subsequent autografting. Cultured epithelial autografts (cultured skin) can be used to cover extensive areas but are expensive, fragile, and prone to loss from infection. They are best used over a scaffolding of intact or allograft dermis, and meticulous wound care is essential for success. A variety of synthetic and processed skin are also available, including synthetic dermis (Integra), acellular dermal matrix (Alloderm), amniotic membrane, collagen-bound polymer membranes (Biobrane, Transcyte), and others. Products still in development combine synthetic dermis with cultured epidermis, providing the potential for future one-step complete skin replacement.¹²⁷ All of these products require experience and skill to utilize successfully.

HEMODYNAMIC SUPPORT

In acutely burned patients blood pressure is sustained by elevated catecholamine levels, though blood volume may remain below normal and hematocrit artificially high. With induction of anesthesia, adrenergic blockade and vasodilation can produce sudden hypotension as these hidden hypovolemia and anemia are revealed. In addition, surgical excision of old or infected burn wounds may stimulate bacteremia and potentiate hemodynamic instability.¹²⁸ The surgical team should prepare for these contingencies by continuing liberal fluid infusions during surgery and anticipating blood loss. Major burn excisions produce significant bleeding, which is often underestimated by surgeons. The blood loss from excision of 1% of the body surface area of an adult has been estimated at approximately 100 mL.¹²⁹ Use of tourniquets for excision, performance of staged excisions, and use of subdermal clysis of epinephrine-containing solutions—the Pitkin procedure—can all help reduce intraoperative bleeding.¹³⁰

TEMPERATURE CONTROL

Burn patients often display mild to moderate fever secondary to hypermetabolism and also have accelerated evaporative heat loss. In the operating room, exposure and suppression of metabolism increase the risk of hypothermia, which can be very hard to correct. Temperature should be monitored carefully, patient warming devices should always be used in the operating room, and the room itself should be kept warm. Limiting operations to 2 to 3 hours is also helpful in avoiding hypothermia.

BURN PHARMACOLOGY AND ANESTHESIA

Depolarizing muscle relaxants (succinylcholine) should not be used in patients with acute injuries,¹³¹ but burn patients are also relatively resistant to nondepolarizing agents and frequently require increased dosage. Induction agents that produce vasodilation, such as propofol, may potentiate hypotension, and should be used with caution. Ketamine maintains hemodynamic stability, and can be used effectively in surgery or for bedside procedures and dressing changes.¹³² Pharmacokinetics and dynamics of many other drugs are also significantly altered in burn patients.¹³³ Increased volume of distribution, decreased albumin binding, and increased renal blood flow necessitate monitoring and individualized dosing of many drugs.¹³⁴

PAIN CONTROL

Pain management is notoriously difficult in burn patients, who often require remarkable quantities of narcotics and sedatives throughout their hospital course. Although altered pharmacology undoubtedly plays a role in this process, extreme levels of sustained pain are typical, and tachyphylaxis often develops during long-term administration of opioids. Patient-controlled analgesia (PCA) can be effective, but use may be limited by impaired consciousness and hand function.¹³⁵ Nonopioid analgesics such as ibuprofen and toradol can be useful adjuncts in patients with cutaneous injuries. Finally, behavior modifications such as relaxation therapy, hypnosis, and virtual reality can be extremely helpful in overcoming the anxiety of dressing changes and physical therapy. Careful assessment of pain and anxiety and individualized dosing regimens are essential for successful management of burn patients.¹³⁶

PULMONARY MANAGEMENT

A variety of pulmonary problems occur frequently in burn patients and can require simultaneous treatment. Initial airway compromise, discussed previously, can be isolated and self-limited, but frequently contributes to pulmonary infection and inflammation. Acute respiratory distress syndrome (ARDS) can occur in the absence of inhalation injury, or components of both disorders can coexist and complement each other. Pulmonary edema or large pleural effusions can complicate fluid resuscitation. Aspiration, narcotic-induced respiratory depression, atelectasis and immobilization from bed rest, associated chest trauma, pulmonary thromboembolism, barotrauma, and pneumothorax/hemothorax following central line placement are all encountered in the management of major burns.

Chapter 48 provides a detailed discussion of the pathophysiology and treatment of the pulmonary complications of burn injury. Recent evidence suggests that inadequate fluid resuscitation may actually accentuate pulmonary damage¹³⁷; burn patients with inhalation injuries require increased resuscitation volumes⁵⁹ and should be resuscitated at least as aggressively as other burn patients. Pulmonary artery catheterization may be helpful in patients with severe lung injuries who require high ventilator pressures. Although colloid-based resuscitation may be associated with persistently increased extravascular lung water,⁹⁰ this does

not appear to be the case with crystalloid, even in patients who require substantially more fluid than Parkland requirements.⁷⁴

A number of reports have focused on techniques to improve oxygenation in burn patients with severe acute lung injury, including extracorporeal membrane oxygenation,¹³⁸ inhaled nitric oxide,¹³⁹ and novel ventilator strategies such as high-frequency volume diffusive,¹⁴⁰ oscillation,¹⁴¹ or percussive ventilation.¹⁴² However, these modalities are limited in their availability and usefulness, and clear-cut indications for each have not been developed. The use of permissive hypercapnia may be beneficial,¹⁴³ though other protective lung strategies have not been evaluated in burns. The vast majority of burn patients can be managed effectively with conventional ventilation techniques, and death purely from hypoxia is rare.

Multiple organ failure is the most common cause of death in burn patients,^{144,145} very frequently triggered by ongoing pulmonary infection, which can be severe and persistent.¹⁴⁶ This pneumonia is usually ventilator associated; intubation facilitates contamination of the lower airways already primed for infection by the mucosal sloughing, mucous plugging, and atelectasis caused by inhalation injury. Frequent cultures and aggressive antibiotic use are necessary for successful treatment. The use of ventilator bundles, including frequent suctioning and chest physiotherapy, elevation of the head of the bed, closed suction techniques, postpyloric feeding, and frequent oral care, may also be helpful.¹⁴⁷ The use of heparin and acetylcysteine aerosols—sometimes combined with bronchodilators—to liquefy and mobilize casts and debris has shown some promise in pediatric patients.¹⁴⁸ Improved mobilization of secretions may also be the mechanism by which percussive or oscillatory ventilation is beneficial.¹⁴² Fiberoptic bronchoscopy and bronchoalveolar lavage can be used both for diagnosis of pneumonia and as a therapeutic maneuver to clear tenacious plugs and improve ventilation.¹⁹ Based on limited evidence, neither corticosteroids nor prophylactic antibiotics appear to be helpful in treating respiratory failure or preventing pneumonia.¹⁴⁹ The performance of tracheostomy in patients who fail initial attempts at extubation may or may not reduce infections¹⁵⁰ but unquestionably provides a more comfortable and secure airway for long-term ventilator support.

CARDIOVASCULAR COMPLICATIONS AND CARE

As mentioned previously, the immediate response to burn injury consists of reduced cardiac output and increased peripheral resistance, followed by gradual return of both values to near-normal at the end of resuscitation, after which markedly elevated cardiac output and reduced peripheral resistance persists through wound coverage and into rehabilitation (see Fig. 67.5). This response is so characteristic that invasive hemodynamic monitoring is rarely needed during resuscitation.

Catecholamine stimulation of cardiac function often results in hypertension, which can be difficult to manage, as well as sustained tachycardia and tachyarrhythmias. Beta blockade is useful in treating these problems, and may be indicated for routine administration as well. Beta blockers

are tolerated well in this situation, and may even contribute to improved outcomes.¹⁵¹

Hypotension can also occur in burn patients during acute care. Obligatory postresuscitation diuresis coupled with increased evaporative and metabolic fluid losses favors development of occult volume depletion. Progressive hyponatremia or azotemia and sustained tachycardia provide clues to this diagnosis, which may require aggressive fluid support. Persistent hypotension should lead to a search for sepsis. Invasive monitoring may be helpful in this setting as well; however, the classic hemodynamic picture of sepsis—increased cardiac output and reduced peripheral resistance—is also the characteristic postburn response, so that such monitoring will likely be more useful in guiding therapy than in diagnosis.

ADRENAL INSUFFICIENCY

Recent studies have demonstrated a surprisingly high frequency of absolute or relative adrenal insufficiency in critical care patients, including burns, which may increase mortality risk from shock and sepsis.^{152,153} However, the quoted incidence of this problem has varied greatly, depending on the diagnostic criteria used and the populations studied.¹⁵⁴⁻¹⁵⁷ No systematic evaluation of adrenal insufficiency has been conducted in burn patients. The incidence of this complication remains unknown,¹⁵⁸ but may be more common than previously suspected, and should be considered in burn patients with refractory hypotension.

INFECTION CONTROL

BURN WOUND INFECTIONS

Historically overwhelming burn wound sepsis was a major cause of death in patients who survived resuscitation. Over the past 50 years, the use of systemic and topical antibiotics coupled with surgical excision and skin grafting has dramatically decreased this problem. However, infection in burn wounds remains an important source of morbidity and mortality risks. As with other infections, the development of increasingly effective antibiotics has been matched by rapid adaptation of microbial pathogens. The initial use of antibiotics in World War II controlled *Streptococcus* and *Staphylococcus* infections, but these were supplanted by gram-negative organisms, particularly *Pseudomonas*. In the 1960s and 1970s, development of silver nitrate solution, mafenide acetate (Sulfamylon) and silver sulfadiazine (Silvadene, Thermazene) were effective in combating these infections, but microflora continued to evolve. Today, burn wound infections are increasingly caused by multiply resistant gram-negative organisms, *Acinetobacter*, methicillin-resistant *Staphylococcus*, *Candida*, and fungi.¹⁵⁹ Individual patients may display a similar progression of wound colonization as therapy and antibiotic administration continue.

Established principles of infection control remain a critical component of burn care. Essentially every open wound should be treated with topical agents until healed. The time-tested agents sulfadiazine and mafenide remain effective against a wide range of bacteria, and still constitute the first line for acute burn treatment despite some limitations. Silver sulfadiazine has been associated with neutropenia, though this is usually a transient phenomenon in the early

postburn period (see later). Mafenide is a carbonic anhydrase inhibitor that can generate significant metabolic acidosis if used on large areas and has also been linked to the emergence of fungal infections.¹⁶⁰ A number of newer topical agents are now available, including silver-containing dressings (Acticoat, Acquacel-Ag), cerium-silver nitrate, mupirocin (Bactroban), chlorhexidine, betadine, and others. The choice of agent and technique should be adjusted based on culture results and wound appearance, and can often be reduced as wounds heal. Silver-containing agents and topical antifungals such as nystatin are effective against yeast and mold infections, and antibiotic solutions including mafenide and silver nitrate are widely used to soak fresh skin grafts and some skin substitutes. The so-called melting graft syndrome has been attributed to chronic infection with *Staphylococcus* species¹⁶¹; topical mupirocin may be particularly effective in this setting.

In addition to topical antibiotics, meticulous wound cleansing and debridement should be performed at least daily and wounds inspected carefully. Findings suggestive of invasive infection include green or black discoloration, purulent exudate, extending erythema or tissue necrosis, conversion of superficial-appearing burns to deep wounds, development of satellite lesions (ecthyma gangrenosum), and loss of vascularized skin grafts. Any of these findings should prompt careful culturing of wounds, escalating or changing topical and systemic antibiotics, and possibly surgery.

Surface cultures of burn wounds will identify dominant organisms, but cannot distinguish between invasive infection and colonization. Burn wound biopsies can be obtained for quantitative culture; bacterial counts of 10^5 per gram of tissue or more has been used as a criterion for invasive burn wound sepsis. However, false-positive results are frequent; wounds may be heavily colonized without bacterial invasion, and biopsies must be obtained in exactly the right place.¹⁶² Histologic demonstration of organisms penetrating into viable tissue and capillaries remains a valid diagnostic finding.¹⁵⁹ However, many centers lack an experienced pathologist to read these samples accurately, so routine biopsies are now used infrequently. Daily examination of wounds and clinical suspicion remain the most important tools for prompt diagnosis of burn wound infection. Once detected, burn wound sepsis is best treated by aggressive, total wound excision, broad-spectrum systemic coverage, and topical antibiotic soaks in preparation for allograft or autograft placement. Burn wound sepsis is an extremely serious complication and should involve every member of the burn team.

OTHER INFECTIONS

Modern methods of infection prevention and control have contributed to decreased rates of many types of infections in burn patients. With the decline in burn wound infections, pneumonia has emerged as the most common infection in burn patients. Central venous catheter infections—particularly from *Candida*—also remain a constant threat¹⁶³ and can contribute to bacterial endocarditis, particularly if lines are allowed to reach the atrium or ventricle.¹⁶⁴ Neither routine catheter changes nor rewires have been shown to decrease infectious risks.¹⁶⁵ The current use of peripherally

inserted central catheters (PICC lines) may or may not reduce the risks of catheter-related infection,¹⁶⁶ but regardless of the line or site used, adherence to accepted principles of catheter placement and care¹⁶⁷ and prompt removal of catheters when possible should be practiced. Improved wound management, nutrition, and hygiene have all but eliminated such historically important infections as suppurative thrombophlebitis, chondritis of the ear, and suppurative parotitis as clinical problems.

Diagnosis of infection can be difficult in burn patients. Fever, leukocytosis, and tachycardia are all normal consequences of acute burn injury, and standard criteria for the diagnosis of systemic inflammatory response syndrome (SIRS) and sepsis are difficult to interpret.¹⁶⁸ Low-grade fever may be sustained during acute treatment, but any increase in temperature above 38.5°C , especially when accompanied by increases in white blood cells (WBCs) or heart rate, should prompt an evaluation for infection, including appropriate cultures. The once-common policy of obtaining routine surveillance cultures of blood, urine, or wounds has been shown to have relatively low yield and a high incidence of false-positive results.¹⁶⁹ Some units use swab cultures to detect colonization and to track dominant flora for epidemiologic reasons. The value of measuring specific biomarkers to detect infection, including C-reactive protein and procalcitonin, has been inconsistent and remains controversial.^{170,171}

Systemic prophylactic antibiotics have not been shown to reduce burn wound or other infections and should not be used.^{172,173} As in all ICU patients, antibiotic use should be guided by the clinical situation and culture results. As noted previously, burn patients often exhibit abnormal drug kinetics and require increased antibiotic dosing and careful monitoring of antibiotic efficacy. The clinical pharmacist is an essential member of the burn team for this and other reasons. The isolation of burn patients through universal precautions and the separation of infected patients by cohort nursing should be practiced as routine components of infection control. The practice of selective digestive decontamination in burn patients is controversial; although some centers report benefits,¹⁷⁴ and some no effect,¹⁷⁵ from this time-consuming technique, it is not routinely practiced in U.S. burn centers.

METABOLIC SUPPORT AND GASTROINTESTINAL MANAGEMENT

THE HYPERMETABOLISM OF BURN INJURY

Burns induce the greatest hypermetabolic response of any injury. This response typically follows the ebb and flow pattern described over 70 years ago,¹⁷⁶ in which initial (24-72 hours) reduced energy expenditure is followed by increasing metabolism, which peaks 10 to 14 days after injury and then tapers slowly as wound healing progresses. The degree of hypermetabolism correlates with burn size but appears to level off with burns of 40% to 50% TBSA, above which no further increase is seen.¹⁷⁷ This response is sustained by the secretion of catecholamines, cortisol, and glucagon that persists until after wounds are closed. Together these hormones accelerate catabolism through breakdown of skeletal muscle, reduced uptake of fats, and opposition to the effects

of insulin.^{178,179} The result is obligatory muscle wasting to support gluconeogenesis; lipids have very little protein-sparing effect, and even exogenous glucose is limited in its ability to prevent protein wasting.¹⁸⁰

In the 1970s burn patients frequently demonstrated prolonged calorie and protein consumption that exceeded twice normal and caused fatal inanition within a few weeks of injury.¹⁸¹⁻¹⁸⁴ Modern burn treatment—aggressive excision and wound coverage, control of sepsis and pain, mechanical ventilation, and improved environmental control—have all helped reduce both the duration and magnitude of this response.^{177,185,186} Nonetheless, significant hypermetabolism persists well after burn wounds are closed, and careful nutritional support is a requirement for the successful care of burn patients.¹⁸⁷

ROUTE AND TIMING OF NUTRITIONAL SUPPORT

The superiority of enteral nutrition is widely accepted,¹⁸⁸ and may be especially true for burn patients. Enteral nutrition nourishes bowel mucosa, preserves blood supply, reduces permeability, and improves associated immune function.¹⁸⁹⁻¹⁹¹ In trauma and ICU patients, early and aggressive enteral nutrition appears to decrease infectious complications, but total parenteral nutrition (TPN) has been associated with an increased mortality rate in burn patients,^{192,193} and it also promotes development of fatty liver.¹⁹⁴ It may even be preferable to withhold nutrition entirely for limited periods, rather than use TPN.

Enteral feeding should begin as quickly as practical following injury, especially if patients will not be able to eat within 5 to 7 days. In contrast to early studies,¹⁹⁵ immediate enteral feedings have not been consistently shown to reduce hypermetabolism,¹⁹⁶ but do decrease calorie deficit and improve nitrogen balance.^{197,198} Feedings can be started within a few hours of injury, and continued even through surgical procedures.¹⁹⁹ The routine use of promotility agents has not been studied in burn patients²⁰⁰; it is also unclear whether small intestinal feedings are superior to gastric feedings; both can have complications, and both require careful monitoring.

ENERGY REQUIREMENTS

Dozens of regimens have been used to estimate the caloric needs of burn patients, including the famous Curreri formula.²⁰¹ However, static formulas cannot accommodate the major fluctuations that occur over time and between individuals of different ages and burn sizes.²⁰² In addition, because modern burn treatment has reduced hypermetabolism, older formulas overestimate requirements significantly.²⁰³ Current recommended caloric intake for adults with major burns is 120% to 150% of Harris-Benedict estimates of basal needs.²⁰⁴ Many centers also use indirect calorimetry to measure energy expenditure and to detect significant under- or overfeeding.²⁰⁵ Regardless, support should still be increased during periods of peak energy expenditure to avoid underfeeding, and reduced later to avoid overfeeding.

Whatever regimen is chosen, the practical difficulties of delivering nutritional support are substantial.^{206,207} Interruptions in feedings, fluctuations in energy consumption caused by fever and activity, and delivery of empty calories in glucose solutions all frustrate attempts to tailor

individual nutrition exactly, which may explain why the superiority of indirect calorimetry-based nutrition has not been proved.²⁰² Involvement of the team—including a dietician—in implementing, assessing, and adjusting feedings is probably more important than adherence to predetermined estimations.²⁰⁸

ENTERAL FORMULAS

Chapter 82 provides details on the composition of many commercially available enteral formulas which can be used in burn patients. Specific components of effective enteral formulas include the following:

Carbohydrates and Glucose Control

The catabolism of burn injury makes carbohydrates the preferred energy source, but also worsens hyperglycemia. Recent studies have demonstrated the value of meticulous glucose control in ICU populations in reducing organ failure, length of stay, and inflammation.^{209,210} These benefits are likely seen in burn patients as well,²¹¹ but hormonally mediated resistance to insulin—the so-called diabetes of injury—makes attaining control a major challenge. Many burn units use hyperglycemia protocols, which require frequent (or continuous) dosing of insulin and careful monitoring. Oral hypoglycemics appear helpful in this effort²¹²; in addition, giving limited calories as fat helps reduce the glucose burden required by these patients.

Fat

A certain (small) quantity of dietary fat is an essential nutrient. Lipolysis is suppressed in burn patients, as is the ability to utilize exogenous fat as an energy source. Fat intake should be restricted to less than 30% of total nonprotein calories, or about 1 g/kg/day²¹³ or less^{214,215}; withholding fat entirely from TPN for substantial periods may be beneficial.^{188,216} In addition, products high in ω -3 free fatty acids (FFAs) and correspondingly low in ω -6 FFAs may improve glucose control and reduce infections.^{217,218} Most clinical experience has been obtained with the use of immune-enhancing diets (IEDs) (see later) in which the effects of individual components have been difficult to assess.

Protein

Accelerated proteolysis is often the most important characteristic of burn-induced hypermetabolism. A major goal of nutrition is to reduce or replace protein losses, which can exceed $\frac{1}{2}$ lb of lean body mass per day. Providing adequate calories alone will not reduce muscle breakdown,²¹⁹ so increased protein must be provided as well. Protein requirements increase with burn size^{220,221}; appropriate provision of dietary protein has resulted in reduced infections and a lower mortality rate in patients with major injuries.²²² Current recommendations are 1.5 to 2.0 g of protein/kg/day (up to 3.0 g/kg/day in children),^{205,208,223} which corresponds to a nonprotein calorie/nitrogen ratio of 100:1 or less. Nitrogen balance should be monitored regularly.

Specific Amino Acids

The amino acids arginine (Arg) and glutamine (Glu) play enhanced roles in critical illness. Both are depleted rapidly in burn patients, and are considered conditionally essential.^{219,224} Glutamine is important in energy transport, as a

precursor of glutathione²²⁵ and as a nutrient for enterocytes, helping to preserve bowel integrity and limit permeability.²²⁶⁻²²⁸ In burn patients provision of up to 25 g Glu/day, given parenterally²²⁹ or enterally,²³⁰ has been associated with improved visceral protein levels and reduced infectious mortality rate and length of stay. Glutamine supplementation has been recommended¹⁸⁸ but is not routinely practiced. Glutamine is almost totally absent from TPN formulas, which may explain some of the benefits of enteral nutrition in burn patients.

Arginine enhances natural killer cell function and nitric oxide (NO) synthesis, promoting inflammation and resistance to infection.^{231,232} Specific studies of arginine supplementation have not been performed in burn patients, but arginine has been incorporated into complex immune-enhancing diets (IEDs) containing ω -3 FFAs, arginine, glutamine, and RNA, among other components.²³³ These diets have shown benefits in some surgical populations,²³⁴ but deleterious or no effects in patients with sepsis or pneumonia,²³⁵ and their widespread use has been questioned.¹⁸⁸ Few data are available on IEDs in burn patients,²³⁶ but the mixed results in other groups suggest that components should be studied separately before incorporating them into cocktails with even more unpredictable effects. Most burn centers simply use high-protein diets rather than these specialized and expensive formulas.

Other Nutrients

A number of micronutrients—including vitamins A, C, and D, iron, zinc, and others—are important in wound healing and may be depleted following burn injury,²³⁷ and some supplementation has been recommended.²³⁸ Many centers simply administer multivitamins, which is probably adequate.^{178,239} Commercial enteral formulas also contain far more than the recommended daily dietary allowances of many vitamins and trace elements.

MONITORING NUTRITIONAL SUPPORT

Because burn injury alters many parameters of nutritional status, monitoring nutrition can be as difficult as providing it. For example, substantial weight gain invariably accompanies fluid resuscitation,²⁴⁰ although overfeeding can increase body fat even as protein stores are depleted.^{241,242} As a result, patients have often lost more lean body mass than is reflected by weight alone.²⁴³ Nitrogen balance studies can be useful, but sedation and bed rest make attaining positive nitrogen balance difficult,²⁴⁴ emphasizing the need to continue physical therapy even during acute care. Serum protein markers are often distorted; levels of albumin,²⁴⁵ prealbumin, and transferrin^{205,246} fall quickly following injury, and recover only very slowly even with appropriate nutrition. Perhaps the best marker of nutritional adequacy in burn patients is their overall status, including vital signs, wound healing, and functional improvement. Body weight, nitrogen balance, and protein markers may be most useful in tracking trends in individuals.²⁴⁷

MODULATION OF HYPERMETABOLISM

Burn-related hormonal changes complicate the provision of nutritional support, but also provide mechanisms by which hypermetabolism can be manipulated. Recent studies have shown promising results, and suggest that manipulation of

the metabolic response to injury may become routine in the future. A variety of approaches have been utilized, including beta blockade with propranolol, low-dose insulin infusions, use of counterregulatory hormones such as insulin-like growth factor-1 (IGF-1), or anabolic agents such as testosterone and oxandrolone.²⁴⁸ The use of propranolol appears to be a safe, low-cost way to ameliorate both the cardiovascular response and hypermetabolic muscle wasting that occur during acute burn care.²⁴⁹ Administration of the synthetic oral androgen oxandrolone has been shown to reduce muscle breakdown, speed rehabilitation, and lead to decreased length of stay in hospitalized patients.^{250,251} Although none of these therapies is now routine, they are becoming more widespread. Recommendations for their routine use will need to await larger controlled trials to demonstrate efficacy.

GASTROINTESTINAL COMPLICATIONS IN BURN PATIENTS

Although the incidence of most gastrointestinal (GI) complications has decreased dramatically with improved resuscitation and control of infection, a number of problems are frequent or serious enough to deserve discussion.

Acute Cholecystitis

Cholecystitis—usually acalculous—can have a number of causes, including gallbladder ischemia from shock and dehydration,²⁵² biliary stasis from narcotics and TPN, bile pigment loads from hemolysis and transfusion, and bacterial seeding from sepsis. With more effective control of these factors, acute cholecystitis is now rare; a recent review documented just 20 cases among 10,762 acutely burned patients (0.18%), with progressive declines in recent years.²⁵³ Fever, leukocytosis, feeding intolerance, and abdominal pain are characteristic findings, though they may be difficult to sort out in acutely ill patients. Ultrasound and computed tomography (CT) scanning are preferred for confirmation of diagnosis; biliary scintigraphy can have a high false-positive rate. Treatment has traditionally consisted of prompt cholecystectomy, though placement of cholecystostomy tubes under ultrasound guidance can provide definitive treatment in many patients.²⁵⁴ With prompt diagnosis, the mortality rate from this complication should be low.

Hepatic Enzyme Elevation

Immediately following burn injury, hemolysis and ileus can contribute to a cholestatic picture, which should resolve within a few days. Some degree of chronic fatty infiltration of the liver may be inevitable in patients with major burns, and mild enzyme elevations are often seen, which is exacerbated by overfeeding and the use of TPN.¹⁹⁴ Severe hepatic steatosis may be both a cause and consequence of sepsis, and correlates with increased mortality rate.

Pancreatitis

Pancreatitis can also result from systemic hypoperfusion and secondary sepsis. In contrast to cholecystitis, the incidence of pancreatitis may be increasing as more severely injured patients now survive burn shock. Ryan and colleagues documented hyperamylasemia in 40% of patients with large burns, with an associated increased mortality rate and length of stay,²⁵⁵ although pancreatic pseudocysts and

abscesses were quite rare. Pancreatic enzymes should be measured in patients with feeding intolerance, abdominal pain, or nausea; in many cases, transient bowel rest and fluid support will be effective treatment. Use of TPN should be avoided unless pancreatitis is unusually severe and prolonged.

Gastrointestinal Bleeding

Although the time-honored eponym Curling's ulcer has sometimes been considered a unique entity, burn patients develop the stress ulcerations typical among acutely ill patients. Mucosal erosions and atrophy can occur within 72 hours of injury and progress to large (often multiple) ulcerations of the prepyloric area or duodenum. Their primary cause is thought to be gastric mucosal hypoperfusion from shock or sepsis; the role of *Helicobacter pylori* infection is unclear.^{256,257} Modern treatment strategies including aggressive fluid resuscitation, suppression or neutralization of gastric acid, and early enteral feeding have resulted in a dramatic decline in the incidence of this complication from as high as 86% in early postmortem studies²⁵⁸ to less than 2% today. Bleeding is more frequent with large injuries and in patients with coagulopathy, prolonged mechanical ventilation, and sepsis. Aggressive evaluation of any observed GI bleeding should be undertaken. Most patients can be controlled with endoscopic maneuvers and continuous proton pump inhibitors. Surgery for acute upper GI bleeding is now rarely required.²⁵⁹

Ileus and Intestinal Necrosis

Ileus occurs routinely following acute burns, and oral intake should be withheld at least until resuscitation is completed. Impaired intestinal motility can be aggravated by narcotics, infection, and ventilatory support. Severe colonic ileus—Ogilvie's syndrome—can occur in this setting,²⁶⁰ and overly aggressive enteral feeding can rarely lead to bowel distention, ischemia, necrosis, perforation, and death.^{261,262} For this reason, feedings should be monitored carefully, and held if obstipation, distention, or pain becomes significant. CT scanning can confirm bowel dilatation or free air, in which case immediate laparotomy is mandatory.

Diarrhea

Diarrhea is extremely common with enteral feedings, and can be a major problem in management. The cause is often multifactorial,²⁶³ including high osmotic loads, overfeeding, enteral medications, and infections including *Cytomegalovirus* and *Clostridium difficile*.²⁶⁴ Treatment options include enteral opiates such as Imodium or paregoric or the use of fiber-containing products. However, fiber can clog small-diameter tubes and has been blamed for intestinal distention and necrosis,²⁶⁵ and slowing intestinal transit can potentiate infectious diarrhea. Often simply holding feedings for a few hours will suffice; diarrhea unresponsive to simple measures should prompt a search for infectious causes, inside or outside the bowel.²⁶⁶

HEMATOLOGIC CONSIDERATIONS

RED BLOOD CELLS

Hemoconcentration, which accompanies burn shock, can result in hematocrits of 70% or higher. This will

theoretically produce sludging and increased vascular resistance, though clinical problems with thrombosis are rare. As resuscitation proceeds hematocrits fall progressively, and are usually below normal by the end of 48 hours. Thereafter, anemia often persists or worsens until wound coverage is obtained. Several mechanisms contribute to this finding.²⁶⁷ First, burn injury destroys red blood cells directly; significant hemolysis can occur within minutes of injury and produce hemoglobinuria or jaundice. Burn-induced alterations in red blood cell metabolism result in spherocytosis, increased membrane fragility, and shortened red blood cell survival. Erythropoietic response is blunted, apparently at the stem cell level,²⁶⁸ and erythropoietin supplementation is not helpful.²⁶⁹ Acute hemorrhage from surgery, and more gradual blood loss from wound debridements add to these effects.

The issue of appropriate transfusion trigger is controversial in burn patients. No systematic trial of transfusion thresholds has been performed, and no standard is universally accepted,²⁷⁰ though limited evidence supports the practice of conservative transfusion in burn patients as in other ICU populations. In a multicenter review, Palmieri and coworkers found that transfusions correlated with both mortality risk and infectious episodes in major burns,²⁷¹ which underscores that transfusions should be based on physiologic assessment and not given routinely.

WHITE BLOOD CELLS

Immediately after burn, leukocytosis and WBC demargination are nonspecific components of the stress response. As with red blood cells, WBC numbers decline following resuscitation, reaching a nadir that is often well below normal on postburn days 2 to 5. In the past, this has been attributed to the use of silver sulfadiazine, but this decline appears to occur regardless of whether this topical agent is used and resolves spontaneously. Thereafter, WBC levels reflect systemic infection and stress. Leukocytosis is common with acute infections, but neutropenia is a far more ominous finding in severe sepsis and may suggest bone marrow failure. Granulopoiesis is accelerated following injury, and is mediated at least partially by catecholamines. Treatment with colony-stimulating factors has not been routinely practiced.

PLATELETS

Platelets and coagulation factors are also consumed in the early postburn period; platelet counts below 100,000/ μ L and coagulopathy are common for the first few days, and supplementation may be needed if major excisions are anticipated. Subsequently, both rebound to supranormal levels. During wound coverage, patients may demonstrate platelet counts in excess of 1,000,000/ μ L, and fibrinogen levels may exceed twice normal. These are reactive abnormalities and do not require treatment.²⁷² Platelet counts are a sensitive indicator of infection; a falling platelet count occurring after the first few days should suggest sepsis, and is associated with a poor prognosis.²⁷³

THROMBOEMBOLISM

Systemic inflammation, a hypercoagulable state, and frequent immobilization might all suggest that thromboembolic complications are common in burn patients. In fact,

reported incidences of clinically apparent deep venous thrombosis (DVT) and pulmonary embolism (PE) are low.²⁷⁴ However, prospective evaluation of burn patients suggests an incidence of DVT/PE similar to that of other moderate- to high-risk populations.²⁷⁵ At present, no consensus exists on the issue of DVT prophylaxis in burn patients. Some centers use it routinely, but many centers provide it for high-risk patients, including the obese and patients with large burns, lower extremity burns, or femoral venous lines.

THE REHABILITATION PHASE

Although the focus of this chapter is the acute care of burn patients, it must be remembered that rehabilitation begins at the time of injury. The physical therapist is an essential member of the acute burn team, and therapy should begin before resuscitation is completed. Physical therapy, mobilization, and prevention of skin breakdown and muscle wasting can have profound effects on the overall success of acute burn care. Immobility and inactivity result in rapid depletion of muscle mass and function; other complications include demineralization of bone and pathologic fractures,²⁷⁶ myositis ossificans, and extensive contracture formation. Therapeutic exercise regimens, beginning during acute care and continuing beyond hospital discharge, can result in improved function and well-being, and increased chances of return to independent living.²⁷⁷

KEY POINTS

- Carbon monoxide poisoning and asphyxia are the most immediate causes of death in burn patients exposed to smoke. High-flow oxygen should be administered to all patients immediately.
- Acute airway obstruction can occur at any time during the first 24 hours of injury, even in the absence of smoke inhalation. Early and elective endotracheal intubation should be performed in patients who develop wheezing, stridor, dyspnea, or significant facial swelling.
- Following initial assessment, fluid resuscitation is the primary goal of initial burn treatment. Fluid resuscitation should be instituted using a formula based on body weight and burn size, such as the Parkland formula, and adjusted to maintain urine output of 0.5 to 1.0 mL/hour.
- During the first 8 to 12 hours after burn, crystalloid solutions such as lactated Ringer's solution should be the sole fluids used for burn resuscitation. After that time, the addition of colloid-containing solutions may be helpful in limiting edema in unburned tissues.
- Invasive hemodynamic monitoring with Swan-Ganz catheters and inotropic fluid support should be reserved for problem patients who are not responding to standard fluid resuscitation.
- Edema in both burned and unburned tissue is progressive throughout fluid resuscitation and may

KEY POINTS (Continued)

- progress rapidly. Intubation should be performed if facial swelling is severe or increasing.
- Extremities with full-thickness or circumferential burns should be monitored with measurements of intramuscular pressure, and escharotomies performed if pressures exceed 30 cm H₂O. Fasciotomies should be performed if pressures fail to improve with escharotomy.
- Torso compartment syndromes can present with sudden and life-threatening hypotension, oliguria, and respiratory distress. Bladder pressures should be measured in patients with extensive torso injuries. Torso escharotomies should be performed initially, but decompressive laparotomy may be required in patients with progressive compromise.
- Multiple trauma in burn patients can be managed using standard approaches, as long as fluid resuscitation is continued.
- Surgical excision and skin grafting of burn wounds require specialized attention to fluid support, blood loss, temperature control, and drug pharmacology.
- Pain control is difficult in burn patients, who often require increased quantities of narcotics. Routine pain assessment and individualized dosing are necessary for successful pain control.
- Acute lung injury is the most common organ failure in burn patients, and pneumonia is the most common infection. Meticulous pulmonary toilet, ventilator support, and antibiotic treatment guided by culture results are all important components of care.
- Burn wound infections remain common in burn patients. Careful wound cleansing, debridement, and examination should be performed daily. Burn wound biopsies can be used to confirm diagnosis and direct therapy, but clinical evaluation remains the most important method for diagnosing these infections.
- Suspected or confirmed burn wound sepsis requires immediate excision of the wound, along with topical and systemic antibiotics.
- Aggressive nutritional support of burn patients is an essential component of care. Enteral nutrition should be started immediately after injury, and consist of a high-calorie, high-protein diet that is relatively low in fat. Commercially available tube feedings also contain sufficient vitamins and trace elements for effective support. Use of immune-enhancing diets is controversial.
- GI complications of burn injury can include acalculous cholecystitis, pancreatitis, ileus, and ischemic necrosis of the bowel.
- Prophylaxis against deep venous thrombosis is not routinely practiced in burn patients, but is probably indicated for patients with a prior history of thromboembolism, patients with extensive lower extremity injuries, and those who are obese.
- Rehabilitation is an essential component of burn treatment and begins with initial care.

Laboratory Tests

GASTROINTESTINAL DECONTAMINATION

ENHANCED ELIMINATION

SPECIFIC POISONINGS

Alcohols

Analgesics

Carbon Monoxide

Cardiovascular Drugs

Cyanide

Dietary and Nutritional Agents

Methemoglobin Inducers

Organophosphate and Carbamate Agents

Psychotropic Drugs

Sedatives

Stimulants

Valproic Acid

Poisonings may result from intentional or unintentional ingestion, inhalation, or skin contact. Toxic complications can also result from therapeutic use of medications. Although mortality rate from toxin exposures is low, patients requiring hospitalization are often cared for in the intensive care unit (ICU). Limited evidence-based information on management of poisonings is available because the variety of drugs and doses that patients are exposed to limit the ability to conduct clinical trials of specific interventions. In addition, animal and human volunteer studies fail to fully replicate the clinical situations that are commonly encountered. Therapeutic recommendations are based on extrapolation of data from animal models, human volunteer studies, case reports, pharmacokinetic information, known pathophysiology, consensus opinion, and a limited number of clinical trials. Toxicologists and local poison control centers are valuable sources of additional information for the clinician.

The approach to the poisoned patient requires an organized evaluation and management plan that often requires the input of emergency physicians, primary care physicians, intensive care clinicians, and clinical pharmacists. The basic steps include initial resuscitation and stabilization, diagnosis, gastrointestinal (GI) decontamination and toxin elimination, institution of specific antidotes or interventions, and supportive care. This chapter addresses these components of management in regard to poisonings most likely to be encountered in ICU patients. Although discussed separately, these steps are usually initiated concurrently in a severely ill patient.

RESUSCITATION AND STABILIZATION

The initial management of seriously ill poisoned patients requires assessment of airway patency, breathing difficulties, circulatory problems, and the level of consciousness. These issues, along with immediate resuscitation interventions, are usually addressed in the emergency department but may be continued in the ICU ([Box 68.1](#)).

DIAGNOSIS

HISTORY

A complete history should be obtained regarding the involved substance or substances including the route of exposure, quantity used, time of exposure, form of medication (regular or sustained-release), and chronicity of use to determine the significance of the presenting symptoms. Specifically, the clinician should inquire about the patient's baseline mental and health status and the medical, occupational, and social history. A detailed medication history should include information about over-the-counter, prescription, illicit, and nutritional or herbal medications. Intentional ingestions often involve multiple coingestants or alcohol, or both. Additional or corroborating information should be obtained from family, friends, paramedics, or witnesses, if available. All available containers found at the site should be brought in with the patient.

Box 68.1 Approach to Resuscitation and Stabilization of the Poisoned Patient

Assess airway and breathing:

- Supplemental oxygen for patients with low oxyhemoglobin saturation; FiO_2 1.0 for carbon monoxide or cyanide exposure
- Intubation and mechanical ventilation for airway protection or with obstruction, hypoventilation, or hypoxemia

Assess hemodynamic status:

- Isotonic fluids initially for hypotension; vasopressor if condition is refractory to fluids
- Treat significant arrhythmias

Assess mental status:¹

Consider the following for altered mental status:

- 50% glucose (25–50 g IV)
- Thiamine (100 mg IV)
- Naloxone (0.4–2 mg IV or IM initially)
- Flumazenil (not routinely recommended)*

*See section on benzodiazepines for further information.

PHYSICAL EXAMINATION

The initial physical examination should focus on vital signs and neurologic findings that may provide physiologic clues to the toxicologic cause. Many toxic substances affect the autonomic nervous system, which is responsible for changes in vital signs mediated by the sympathetic and parasympathetic pathways. Attention to these initial and subsequent clinical signs is of paramount importance in identifying patterns or changes suggesting a particular drug or category of drugs (Table 68.1). Changes in the clinical examination after a therapeutic intervention or the administration of an antidote should be noted. Continued monitoring and reevaluation are necessary because drug effects may not be present on initial evaluation.

Altered mental status is common in a toxicologic emergency. A detailed assessment of neurologic status should be made to determine if there is any alteration in level (stupor/coma or agitation) or content of consciousness (confusion/delirium).¹ The evaluation should include an assessment of pupillary reactivity, ocular movements, and motor responses. Ruling out structural versus toxic or metabolic reasons for the altered state is important. Drug-induced seizures are often difficult to treat and may respond only to specific antidotal therapy. In general, benzodiazepines are more effective in terminating drug-induced seizures than other agents.

Pupils should be assessed for size and reactivity, and ocular movements should be evaluated for the presence of sustained nystagmus. Agents associated with miosis include organophosphates/carbamates (mydriasis also seen), other cholinergic agents, opioids, acetone, clonidine, phencyclidine, phenothiazines, and nicotine. Both anticholinergics and sympathomimetics may cause mydriasis; the pupils are reactive to light with cocaine but unreactive in diphenhydramine overdose. Opioid withdrawal may also result in dilated pupils. The assessment may be difficult in the setting of multiple coingestants, whereby the response may be blocked

Table 68.1 Drug Effects on Vital Signs

Increased	Decreased
Blood Pressure	
Amphetamines	Antihypertensive agents
Anticholinergics	Cyanide
Cocaine	Cyclic antidepressants
Ephedrine	Ethanol, other alcohols
Phencyclidine	Iron
Sympathomimetic agents	Opioids
	Organophosphates/carbamates
	Sedative-hypnotics
Heart Rate	
Amphetamines	Beta blockers
Anticholinergics	Calcium channel blockers
Antihistamines	Clonidine
Caffeine	Digitalis glycosides
Carbon monoxide	Gamma hydroxybutyrate
Cocaine	Lithium
Cyanide	Opioids
Cyclic antidepressants	Organophosphates/carbamates
Ephedrine	Physostigmine
Ethanol	Sedative-hypnotics
Phencyclidine	
Theophylline	
Respiratory Rate	
Alcohols	Ethanol, other alcohols
Amphetamines	Gamma hydroxybutyrate
Anticholinergics	Opioids
Carbon monoxide	Organophosphates
Hydrocarbons	Sedative-hypnotics
Salicylates	
Theophylline	
Temperature	
Amphetamines	Beta blockers
Anticholinergics	Carbon monoxide
Cocaine	Ethanol
Cyclic antidepressants	Gamma hydroxybutyrate
Lithium	Hypoglycemic agents
Phencyclidine	Opioids
Salicylates	Sedative-hypnotics
Theophylline	

or partially manifested. Horizontal nystagmus is commonly seen with alcohols, lithium, carbamazepine, solvents, and primidone. Phenytoin, sedative-hypnotics, and phencyclidine may cause a combination of vertical, horizontal, or rotatory nystagmus.

The clinical examination should also include evaluation of bowel sounds (decreased/hyperactive), skin (wet/dry), and mucosa (secretions).

TOXIDROMES

A complex of signs and symptoms may be identified by physical examination and grouped into a toxic syndrome, or “toxidrome.” In many cases, recognition of this toxic pattern is more important than identifying a specific offending agent. Identifying a toxidrome enables the clinician to

Table 68.2 Toxidromes

Drug Group	Vital Signs				Additional Manifestations				
	BP	HR	RR	T	Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
Sympathomimetic (adrenergic) agents	±	↑	↑	↑	Altered, agitation	↑	↑	↑	Flushing, potential for seizures
Anticholinergic agents	±	↑	±	↑	Altered, hallucinations	↑	↓	↓	Dry mucous membranes, thirst, flushing, urinary retention
Cholinergic (muscarinic, nicotinic) agents	±	±	—	—	Altered	±	↑	↑	Salivation, lacrimation, urination, emesis, bronchorrhea, fasciculations
Opioids	↓	↓	↓	↓	Altered, sedation	↓	↓	↓	Hyporeflexia
Sedative-hypnotics or ethanol	↓	↓	↓	↓	Altered, sedation	±	↓	↓	Hyporeflexia

BP, blood pressure; HR, heart rate; RR, respiratory rate; T, temperature; ↑, increase; ↓, decrease; ±, variable; —, change unlikely.
 Adapted from Nelson NS, Lewin NA, Howland MA, et al: Initial evaluation of the patient: Vital signs and toxic syndromes. In Nelson NS, Lewin NA, Howland MA, et al (eds): Goldfrank's Toxicologic Emergencies, 9th ed. New York, McGraw-Hill Medical, 2011, p 33.

initiate the assessment, derive a differential diagnosis, and formulate a treatment plan. The most typical toxidromes are listed in [Table 68.2](#).² Importantly, the clinician should note that patients may not present with a classic toxidrome due to variable manifestations of toxins and overlapping features that exist between toxidromes.

LABORATORY TESTS

A laboratory test for a patient exposed to toxic agents should be helpful in diagnosis or monitoring.³ Select laboratory examinations may be used when appropriate to determine the three gaps of toxicology—the anion gap, the osmolar gap, and the oxygen saturation gap. An arterial blood gas (ABG) analysis will identify hypoxemia or hypoventilation, as well as acid-base abnormalities. Agents associated with a gap in oxygen saturation (>5% difference between measured and calculated saturation) include carbon monoxide (CO) and methemoglobin inducers. In these exposures, a pulse oximeter inaccurately reflects the oxygen saturation of tissues and co-oximetry is necessary to identify abnormal hemoglobins. Determination of electrolytes with blood urea nitrogen (BUN) and creatinine will detect renal abnormalities and allow calculation of the anion gap. Some common drugs associated with an anion gap acidosis are listed in [Box 68.2](#). Hypoperfusion must also be considered as a cause of metabolic acidosis. An osmolar gap (>10 mOsm/L) may be caused by any small particle (toxin) that increases the measured osmolality as measured by freezing point depression. Such agents include ethanol, ethylene glycol, glycerol, isopropyl alcohol, mannitol, methanol, propylene glycol, and sorbitol. An electrocardiogram (ECG) should be obtained when potential cardiac toxicity exists.

A qualitative urine drug screen is a combination of tests that serves to identify common drugs encountered in overdoses. However, a “tox screen” is usually unnecessary because the results rarely alter management, many toxins are not detectable, and positive results do not assess severity of

exposure. Quantitative determination of drug/toxin concentrations in blood is indicated by history and clinical examination to diagnose the intensity of toxicity, monitor the treatment or course of a patient, or define indications for specific interventions. Serum concentration measurements may be required as criteria for therapy or to assess the effectiveness of therapy. Because of the ubiquity of acetaminophen in over-the-counter and prescription preparations and the potential for significant morbidity and even death, a level should be obtained in any suspected polydrug ingestion.

GASTROINTESTINAL DECONTAMINATION

GI decontamination techniques in the poisoned patient with an oral ingestion have included gastric emptying procedures (ipecac-induced emesis, gastric lavage), adsorption of drugs (activated charcoal), and increasing transit through the GI tract (cathartics, whole bowel irrigation [WBI]). Use

of these interventions has decreased due to uncertain evidence of benefit and recognition of adverse effects of the techniques.⁴ The consideration of a GI decontamination technique depends on the toxicity of the substance ingested, potential for deterioration in respiratory and mental status, severity of symptoms, dose, time since ingestion, presence of spontaneous emesis, and contraindications of the procedure.

Ipecac, which contains emetic alkaloids, stimulates gastric mucosal sensory receptors and the chemoreceptor trigger zone in the brain to produce vomiting. The amount of ingested drug removed by ipecac-induced emesis is highly variable, and no benefit of ipecac has been confirmed even when administered less than 60 minutes after ingestion. Currently, ipecac is not used in the management of adult poisoning victims.⁵ Complications that have been associated with ipecac administration include aspiration pneumonitis, esophageal rupture, Mallory-Weiss tear, pneumomediastinum, and protracted vomiting that can delay administration of activated charcoal.

Gastric lavage with a large bore (36- to 40-French) orogastric tube is a technique used to empty the stomach of orally ingested substances that can be associated with significant complications. After insertion of the tube, lavage is accomplished with sequential 250 mL aliquots of normal saline or water until no pill fragments are retrieved. Intubation for airway protection is required before the procedure in patients with a depressed level of consciousness or potential for sedation. No clear benefit of gastric lavage has been demonstrated, even when instituted in obtunded patients presenting within 1 hour of ingestion.⁶ Gastric lavage should not be employed routinely in the management of poisoned patients.⁷ In rare circumstances, gastric lavage may be considered with ingestion of a life-threatening amount of toxin when the procedure can be instituted within 60 minutes of ingestion or a significant amount of toxin is still likely to be present in the stomach. The clinician must consider contraindications and the potential risks before performing gastric lavage in an overdose patient. Serious complications include aspiration pneumonitis, esophageal perforation, and cardiovascular instability. Gastric lavage is contraindicated with ingestions of substances such as acid, alkali, or hydrocarbons when the risk of aspiration is increased. Patients with a risk of GI perforation or severe bleeding diathesis or who are combative should also not be subjected to gastric lavage.

Single-dose activated charcoal is one of the more frequently used interventions for GI decontamination. Activated charcoal potentially adsorbs the toxin in the GI tract and minimizes systemic absorption. The optimum dose of activated charcoal has not been established, but the usual dose for adults is 25 to 100 g (1 g/kg). Activated charcoal is not effective in adsorbing iron, lithium, cyanide, strong acids and bases, alcohols, and some hydrocarbons. Some clinical studies examining the use of activated charcoal versus no intervention found no improvement in outcomes.^{8,9} Volunteer studies suggest that the greatest benefit of administering activated charcoal may be within 1 hour of ingestion.¹⁰ Use of activated charcoal may be considered when a potentially toxic amount of a substance adsorbed by charcoal has been ingested within 1 hour.^{11,12} Later administration may be appropriate if clinical factors suggest the ingested substance has not yet been completely absorbed.

Activated charcoal is contraindicated in patients with a depressed level of consciousness unless intubated, when administration increases the risk of aspiration, or the patient is known or suspected to have a GI perforation. Few complications are associated with the appropriate use of single-dose activated charcoal. Emesis has been reported but may be related to sorbitol administered with charcoal or the ingested toxin.

Cathartics have been administered in poisoning ingestions based on the hypothesis that absorption and overall bioavailability of the agent are decreased by reducing contact time in the GI tract. Sorbitol (70% solution with activated charcoal) is the most commonly used cathartic, but magnesium citrate and magnesium sulfate have also been used. No clinical studies have demonstrated beneficial effects of cathartics in poisoned patients. A cathartic alone has no role in the management of poisonings, and even the routine use of a cathartic in combination with activated charcoal cannot be recommended.¹³ If a cathartic is used, only a single dose should be administered. A cathartic should not be administered in patients with ileus, GI obstruction or perforation, recent GI surgery, or hemodynamic instability. Complications of cathartics include nausea, vomiting, and abdominal cramping. Multiple doses of magnesium-containing cathartics may result in significant dehydration and electrolyte abnormalities.

WBI has been proposed as a technique to prevent absorption of ingested poisons by rapidly expelling the bowel contents. WBI involves the enteral administration (usually by nasogastric tube) of large volumes (1 to 2 L/hour in adults) of polyethylene glycol electrolyte lavage solution; this is continued until the rectal effluent is clear or elimination of the toxin has been confirmed. During the procedure, the head of the bed should be elevated to 45 degrees to decrease the likelihood of vomiting and aspiration. No clinical trials have assessed the impact of WBI on patient outcomes. Currently, there are no established indications for WBI, but it may be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, iron, and illicit drug packets.¹⁴ WBI is contraindicated in the presence of ileus, GI obstruction or perforation, GI bleeding, hemodynamic instability, or intractable vomiting. In the patient with decreased level of consciousness or respiratory depression, the airway must be protected before instituting WBI.

ENHANCED ELIMINATION

Multiple-dose activated charcoal (MDAC) therapy involves the repeat oral administration of activated charcoal to prevent absorption of drug that persists in the GI tract and to enhance elimination of drugs already absorbed into the body by functioning as an adsorbent “sink” at several sites in the gut.¹⁵ First, it can interrupt enterohepatic circulation of drugs or metabolites that are actively secreted into bile. Second, it can adsorb drugs or metabolites that enter the gut by active secretion or passive diffusion and prevent reabsorption. Finally, it may prevent desorption of drugs, particularly acidic substances that bind two to three times less avidly to activated charcoal in the alkalotic milieu of the intestinal lumen than in the acidic environment of the stomach. Drugs with a prolonged elimination half-life after

overdose and small volume of distribution are more likely to have elimination enhanced significantly by MDAC.

One suggested regimen for administering MDAC is to follow the initial dose of activated charcoal with 0.5 to 1 g/kg every 4 hours. Alternatively, it is possible to administer charcoal as an aqueous solution by continuous infusion via a nasogastric tube at a rate of 0.25 to 0.5 g/kg/hour (not <12.5 g/hour). Additionally, the smaller doses (and volumes) administered more frequently may reduce the likelihood of vomiting. It may still be necessary to give an antiemetic intravenously to ensure effective administration. The dosing schedule will be dictated by clinical parameters such as patient cooperation, level of consciousness, the presence of ileus and vomiting, laboratory parameters, plasma concentrations of drug, and clinical improvement. Patients receiving MDAC should be monitored carefully for the development of constipation or obstruction and for the prevention of aspiration.

There is no convincing evidence that MDAC reduces morbidity and mortality rates in poisoned patients.¹⁶ However, MDAC may be considered if the patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline and may obviate the need for invasive extracorporeal techniques. Insufficient evidence exists to support routine use of MDAC in ingestions of other substances.

Forced diuresis involves the intravenous (IV) administration of large volumes of isotonic fluids and diuretics to enhance renal excretion of drug or metabolite. This method is of limited clinical benefit and should not be used because of the potential for fluid overload and acid-base disturbances.

Urinary alkalinization is beneficial in increasing renal clearance of weak acids such as salicylates and phenobarbital. These weak acids are ionized at alkaline urine pH, trapped in the renal tubules, and not reabsorbed. Alkalinization can be initiated by adding 88 to 132 mEq sodium bicarbonate to 1 L of 5% dextrose in water (D₅W). Urine pH should be tested every hour, and the rate of the bicarbonate infusion should be titrated to achieve a urine pH of 7.5 to 8.5. Alkalinization may be difficult to achieve if metabolic acidosis is present. Hypokalemia is a common complication and requires correction to facilitate urinary alkalinization. Increasing the urine pH with carbonic anhydrase inhibitors such as acetazolamide is not recommended because metabolic acidosis will worsen. Urine alkalinization can be considered in patients with significant salicylate ingestions who do not require hemodialysis. Phenobarbital poisonings are more effectively treated with MDAC.¹⁷

Hemodialysis is useful to increase the clearance of certain drugs and metabolites, as well as to correct metabolic acidosis induced by some substances. The concentration gradient of the unbound toxin provides the driving force for clearance. The following criteria should be applied to a drug to determine the potential for enhanced elimination by hemodialysis: low volume of distribution (<1 L/kg), single-compartment kinetics, low endogenous clearance (<4 mL/minute/kg), molecular weight less than 500 daltons, water solubility, and low plasma protein binding. Drugs for which hemodialysis should be considered in the presence of a significant intoxication include methanol, ethylene glycol, salicylates, lithium, valproic acid, boric acid, and thallium.

The usual complications of hemodialysis may occur, particularly in unstable patients. Hemoperfusion is a form of extracorporeal toxin removal, whereby whole blood is passed through an adsorbent-containing (charcoal) cartridge. In general, if a compound is well adsorbed by activated charcoal, then charcoal hemoperfusion clearance may exceed that of hemodialysis. In contrast to hemodialysis, substances with a high degree of plasma protein binding can be removed. However, advancements in hemodialysis and the limited availability of hemoperfusion cartridges have resulted in decreased utilization of hemoperfusion. Charcoal hemoperfusion is effective for elimination of carbamazepine, phenobarbital, phenytoin, and theophylline. Lithium and other heavy metals are not well removed by hemoperfusion. Charcoal hemoperfusion is generally performed for 4 to 6 hours at flow rates of 250 to 400 mL/minute. The risks of hemoperfusion are similar to those of hemodialysis. Additionally, hypoglycemia, hypocalcemia, and hypothermia may occur.

Continuous renal replacement therapies have been used less frequently for drug removal in the treatment of poisoning.¹⁸ Clearance rates achieved with these techniques are considerably lower than those achieved with hemodialysis. Such therapy may be instituted after hemodialysis or hemoperfusion to further remove the drug after it slowly redistributes from tissue to blood. This is a potential option for agents such as lithium or procainamide. Continuous renal replacement techniques may be advantageous in hemodynamically unstable patients who cannot tolerate conventional hemodialysis or hemoperfusion. Despite many case reports demonstrating significant drug clearance, there are no data demonstrating that these techniques affect outcome.

SPECIFIC POISONINGS

ALCOHOLS

ETHYLENE GLYCOL AND METHANOL

Methanol and ethylene glycol are toxic alcohols that have similar properties in overdose. Toxicity can occur through ingestion, inhalation, or dermal absorption. Cardiopulmonary and central nervous system (CNS) symptoms are common, and both agents can produce an anion gap metabolic acidosis and an osmolar gap. However, absence of an osmolar gap or anion gap does not exclude a toxic ingestion. The osmolar gap may be normal if all alcohol is metabolized to acid metabolites, and an anion gap may be normal if metabolism of alcohol has not yet produced acid metabolites (e.g., concomitant ethanol ingestion or early presentation). If toxic alcohol ingestion is suspected, regardless of whether the patient is symptomatic, blood should be immediately sent for serum methanol, ethylene glycol, and ethanol levels, and definitive treatment initiated based on the clinical history and acid-base status. Significant toxicity is associated with methanol and ethylene glycol levels greater than 50 mg/dL. The severity of pH, serum bicarbonate, and anion gap abnormalities appears to be directly correlated with the likelihood of survival.

Ethylene glycol is found in antifreeze and deicing solutions. Ethylene glycol causes acidemia as a result of metabolism by alcohol dehydrogenase to glycolic and oxalic acid.

Oxalate crystals in the urine may be detected with a Wood's lamp or on microscopic examination, but they may not be present in the majority of exposed patients. Three classic phases of ethylene glycol toxicity have been described: neurologic, cardiopulmonary, and renal. During the first 0.5 to 12 hours after ingestion, ethylene glycol produces transient inebriation without the usual odor of ethanol, along with GI symptoms (nausea, vomiting). After toxic metabolites form (4 to 12 hours after ingestion), a metabolic acidosis develops along with CNS depression. The CNS symptoms may progress to coma associated with hypotonia, hyporeflexia, and occasionally seizures, meningismus, and cerebral edema. In the second stage (12 to 24 hours after ingestion), tachycardia and hypertension often occur along with progression of metabolic acidosis. Hypoxia may result from aspiration, heart failure, or acute respiratory distress syndrome. Death is most common in this stage. In the third stage (24 to 72 hours after ingestion), oliguria, flank pain, acute tubular necrosis, and renal failure develop.

Methanol is found in windshield washer fluid, solvents, and bootleg whiskey. It is metabolized by alcohol dehydrogenase to formaldehyde, which is then metabolized by aldehyde dehydrogenase to formic acid. Uncoupling of the mitochondrial oxidative metabolism produces lactic acid. The metabolic derangements are caused by lactic and formic acid; the latter is responsible for ocular disturbances. When methanol is ingested, peak levels occur within 30 to 60 minutes but there is often a latent period of about 24 hours (range 1 to 72 hours) before the development of toxic symptoms or metabolic acidosis. GI (abdominal pain, nausea, vomiting), CNS (dizziness, headache, seizures,

coma), and ocular toxicities (blurred vision, photophobia, retinal edema, disc hyperemia, blindness) are seen.

Practice guidelines are available for the treatment of ethylene glycol and methanol intoxication.^{19,20} If the patient has symptoms and is significantly acidemic, sodium bicarbonate may be administered as a temporizing measure to enhance formate and oxalate elimination by ion trapping. Fluid overload and hyperosmolarity may become significant problems as a result of bicarbonate administration. Hydration is helpful because ethylene glycol is well excreted by the kidney as long as renal function is maintained. The definitive treatment of intoxication with methanol or ethylene glycol is inhibition of the alcohol's metabolism and hemodialysis to remove the alcohol and toxic metabolites and to correct metabolic abnormalities. Hemodialysis should be considered for the following conditions: deteriorating vital signs despite intensive supportive care, significant metabolic acidosis (pH < 7.25 to 7.3), blood level of methanol or ethylene glycol higher than 25 mg/dL, or any evidence of renal failure or electrolyte imbalances unresponsive to conventional therapy.^{19,20}

Antidotal treatment of significant poisoning involves inhibition of alcohol dehydrogenase to prevent metabolism of the alcohols to toxic metabolites with ethanol or fomepizole. Ethanol (IV or oral) allows preferential metabolism of ethanol over methanol and ethylene glycol. Ethanol should be administered to maintain a blood level of 100 to 150 mg/dL. A loading dose should be followed by a maintenance infusion according to the established dosing requirements for nondrinkers, drinkers, and during hemodialysis (Table 68.3).²¹ Problems encountered during

Table 68.3 Intravenous Administration of 10% Ethanol

Dosing	Amount (mL) Infused over 1 Hour, as Tolerated, by Body Weight			
	30 kg	50 kg	70 kg	100 kg
Loading Dose*				
Loading dose of 0.8 g/kg of 10% ethanol†	240	400	560	800
Maintenance Dose‡				
	Infusion Rate (mL/hr) by Body Weight			
	30 kg	50 kg	70 kg	100 kg
<i>Normal Maintenance Range§</i>				
80 mg/kg/hr	24	40	56	80
110 mg/kg/hr	33	55	77	110
130 mg/kg/hr	39	65	91	130
<i>Maintenance Dose for Chronic Alcoholic</i>				
150 mg/kg/hr	45	75	105	150
<i>Dose Required during Hemodialysis</i>				
250 mg/kg/hr	75	125	175	250
300 mg/kg/hr	90	150	210	300
350 mg/kg/hr	105	175	245	350

*A 10% vol/vol concentration yields approximately 100 mg/mL.

†For a 5% concentration, multiply the amount by 2.

‡Infusion to be started immediately after the loading dose. Concentrations above 10% are not recommended for intravenous administration.

The dose schedule is based on the premise that the patient initially has a zero ethanol level. The aim of therapy is to maintain a serum ethanol level of 100 to 150 mg/dL, but constant monitoring of the ethanol level is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis.

§Rounded to the nearest milliliter.

Adapted from Howland MA: Antidotes in depth: Ethanol. In Nelson NS, Lewin NA, Howland MA, et al (eds): Goldfrank's Toxicologic Emergencies, 9th ed. New York, McGraw-Hill Medical, 2011, p 1419.

ethanol administration include CNS depression, hypoglycemia, dehydration, and fluctuating serum concentrations. A second IV line using 0.9% sodium chloride may be necessary to avoid development of hyponatremia because of the large free water content and significant hypertonicity (1713 mOsm/L) of 10% ethanol solution. Advance notice should be given to the pharmacy to allow sufficient time to locate enough ethanol for administering and preparing the solution. If IV ethanol is not available, oral ethanol can be used.

Fomepizole, a competitive inhibitor of alcohol dehydrogenase, is approved for use in ethylene glycol and methanol overdose.²² It is easier to administer than ethanol, does not cause sedation, and is associated with fewer severe and serious adverse events.²³ Fomepizole administration should be considered instead of ethanol if the patient develops altered consciousness, seizures, or a significant metabolic acidosis. Although fomepizole appears to be equally effective, there are no data to demonstrate its comparative efficacy or cost-effectiveness. Administration of ethanol or fomepizole should continue after dialysis until the serum ethylene glycol or methanol concentration is undetectable or less than 20 mg/dL or acidosis is resolved and the patient is asymptomatic. In the absence of renal dysfunction and a significant metabolic acidosis, the use of fomepizole potentially could obviate the need for hemodialysis, even though the serum ethylene glycol or methanol concentration exceeds 50 mg/dL.²⁴ If patients with high serum concentrations of ethylene glycol are not treated with hemodialysis, then their acid-base balance should be monitored closely and hemodialysis instituted if a metabolic acidosis develops.¹⁹

Additional therapeutic measures for ethylene glycol ingestions may include thiamine 100 mg IV and pyridoxine 50 mg every 6 hours until the ethylene glycol level is zero and no acidosis persists. If the patient becomes hypocalcemic as a result of precipitation of calcium oxalate crystals, calcium should be replaced. In methanol overdose, it may be reasonable to also administer IV folate (folinic or folic acids) at 50 to 75 mg IV every 4 hours for at least 24 hours to provide the cofactor for enhancing formic acid elimination.

ISOPROPYL ALCOHOL

Isopropyl alcohol may also be ingested, particularly by chronic alcoholics with no access to ethanol. It is found in rubbing alcohol and some hand sanitizers in high concentrations. Oral absorption occurs rapidly (within 0.5 hour), and it undergoes metabolism to acetone, carbon dioxide, and water. Symptoms may include severe abdominal pain, GI bleeding, nausea, and vomiting. Isopropyl alcohol is two to three times more potent than ethanol as a CNS depressant, and acetone is comparable with ethanol. Patients frequently present with headache, lethargy, ataxia, or coma. Respiratory depression occurs secondary to the CNS depression. Laboratory findings include an osmolar gap without a metabolic acidosis. Patients may, however, have a fruity odor on their breath from acetone, and ketonemia and ketonuria may also be present. Treatment is supportive with fluid administration for significant dehydration. Hemodialysis should be considered when isopropyl alcohol levels exceed 400 to 500 mg/dL, evidence of hypoperfusion exists, coma is present, or a failure to respond to supportive therapy is noted.

PROPYLENE GLYCOL

Propylene glycol is another alcohol that can cause toxicity in critically ill patients receiving high doses of IV medications containing the alcohol as a solvent. Medications that contain propylene glycol include lorazepam, diazepam, phenobarbital, pentobarbital, nitroglycerin, phenytoin, esmolol, etomidate, and sulfamethoxazole/trimethoprim. Propylene glycol toxicity is more commonly observed with lorazepam because of the use of high doses in some patients, the frequency of use for sedation in ICUs, and the high concentration of propylene glycol—approximately 830 mg/mL.²⁵ Common manifestations of propylene glycol accumulation are anion gap metabolic acidosis and increased osmolar gap.²⁶ Additional toxicities include renal dysfunction, hemolysis, cardiac arrhythmias, seizures, and CNS depression or agitation. Clinical studies suggest that an elevated osmolar gap correlates with propylene glycol accumulation. Accumulation can occur when doses of lorazepam exceed 0.1 mg/kg/hour and when renal or hepatic insufficiency is present. Although toxicity is more common after long periods of lorazepam infusion (>3 days), toxicity has occurred with short-term, high-dose use. The treatment of choice is to stop the lorazepam infusion and sedate with an agent that does not contain propylene glycol. Hemodialysis removes propylene glycol but is usually not required unless severe renal dysfunction develops.

ANALGESICS

ACETAMINOPHEN

Acetaminophen (*N*-acetyl-*p*-aminophenol [APAP]) is present in a large number of prescription and over-the-counter medications and is frequently a coingestant with other drugs. In addition, unintentional overdoses result from patients unknowingly ingesting multiple products containing acetaminophen (particularly acetaminophen-narcotic combinations). Because APAP overdose may result in significant hepatotoxicity and even death that is preventable, it is important to recognize and initiate appropriate therapy. With higher doses of APAP, a greater proportion is hepatically metabolized by the cytochrome P-450 system of mixed function oxidases (CYP450) to the toxic metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which can result in cell injury and death. Hepatic glutathione facilitates detoxification and elimination of NAPQI with therapeutic doses of APAP, but glutathione supply is overwhelmed in APAP overdoses. The clinical course of APAP toxicity has been divided into stages on the basis of the development of hepatotoxicity (Table 68.4).²⁷

If possible, an estimate of the quantity and dosage form of APAP ingested and the time of ingestion should be obtained. In adults, hepatic toxicity can occur after ingestion of more than 7.5 to 10 g during 8 hours or less but has been reported with exposures of 4 g. The maximum daily dose of acetaminophen has been reduced to 3 g because of concerns for toxicity.²⁸ The risk of toxicity may be increased in patients with low glutathione stores (malnutrition, fasting state, chronic alcoholism) or induction of CYP450 enzymes (chronic alcoholism, phenytoin or carbamazepine use). For patients with a recent single, acute ingestion, an acetaminophen level should be obtained at least 4 hours after ingestion. Liver enzymes only need to be evaluated if the APAP

Table 68.4 Stages of Acetaminophen Toxicity

Stage	Time Course (after Ingestion)	Characteristics
I	0-24 hours	Asymptomatic or nausea, vomiting; normal LFTs
II	24-72 hours (latent stage)	Right upper quadrant pain; abnormal LFTs and PT; renal dysfunction possible
III	72-96 hours (hepatic stage)	Encephalopathy, jaundice, bleeding, renal dysfunction; maximal hepatic injury, synthetic dysfunction
IV	4 days-2 weeks (recovery stage)	Recovery of liver function

LFT, liver function tests; PT, prothrombin time.

level indicates potential toxicity or the clinical examination suggests hepatic injury. If the time of ingestion is unknown, an APAP level should be obtained on admission. An APAP level and liver function tests should be determined in patients presenting late, patients with multiple ingestions over time, or chronic ingesters of APAP.

Activated charcoal does adsorb acetaminophen, and it is reasonable to administer charcoal up to 2 hours after ingestion. Acetaminophen is absorbed rapidly from the GI tract, so later use of charcoal is not warranted unless gastric emptying is likely to be delayed. Administration of activated charcoal will not interfere with subsequent administration of oral *N*-acetylcysteine (NAC) therapy.

NAC is the antidote for APAP poisoning, but the optimal route and duration of treatment are still debated.²⁹ NAC limits toxicity by combining with NAPQI and by serving as a precursor of glutathione, which inactivates NAPQI. For patients with a single, acute ingestion of APAP, the serum acetaminophen level assessed at least 4 hours after ingestion is compared with the Rumack-Matthew nomogram. Treatment with NAC is initiated in the United States if the value falls above the lower possible hepatotoxicity line. Only the initial APAP level is used in making the decision to initiate or continue NAC treatment. Subsequent levels are unnecessary unless extended-release preparations are ingested (see following). The Rumack-Matthew nomogram is not useful for patients with multiple ingestions of APAP over time, chronic ingesters, or those ingesting extended-release forms (see following discussion). If acetaminophen levels are not available, NAC treatment should be initiated if more than 150 mg/kg or 10 g acetaminophen is ingested. For extended-release APAP, a second level 4 hours after an initial nontoxic level should be evaluated to assess for delayed absorption. If the second value is above the lower line on the Rumack-Matthew nomogram, NAC is initiated.

NAC is most effective in preventing toxicity if administered within 8 hours of ingestion. NAC therapy can be initiated pending results of the acetaminophen level if the

patient is presenting late or APAP level results will be delayed. The oral regimen for NAC includes a loading dose of 140 mg/kg followed by 17 oral maintenance doses of 70 mg/kg administered 4 hours apart (72-hour regimen). Due to the odor of the oral form, a nasogastric tube may need to be placed for administration, and antiemetic therapy may be necessary to control vomiting that occurs in up to 50% of patients. If the patient vomits the loading dose or any maintenance dose within 1 hour of administration, the dose should be repeated. IV NAC is administered as a loading dose of 150 mg/kg over 60 minutes followed by 50 mg/kg infused over 4 hours and then 100 mg/kg infused over 16 hours (21-hour regimen). Anaphylactoid reactions may occur in 14% to 18% of patients with IV NAC. Oral and IV regimens of administering NAC are similar in efficacy.³⁰ However, the oral regimen may be more appropriate in patients who present later after ingestion (>18 hours) and when large amounts of APAP are ingested due to the higher dose of administered NAC.^{31,32} If the patient has a serum APAP level in the potentially toxic range, the aspartate aminotransferase (AST) or alanine aminotransferase (ALT) level should be evaluated daily. If abnormal, additional tests such as bilirubin, prothrombin time, creatinine, BUN, blood glucose, and electrolytes should also be obtained. In patients with elevated liver enzymes, NAC may be continued beyond the full course of therapy until transaminases are decreasing.

Chronic ingesters of APAP or patients with multiple ingestions over time are problematic when determining the need to administer NAC. Presentation beyond 24 hours after ingestion makes the APAP level essentially useless, and there are no established guidelines for administration of NAC in these circumstances. A marker of toxicity that may be useful is the evaluation of AST and ALT. If enzymes are elevated at the time of presentation (>50 IU/L) or the APAP level is greater than 10 µg/mL (>10 µmol/L), a course of NAC should be strongly considered.³³ A course of NAC should also be administered to patients with hepatic failure caused by APAP.

Patients with evidence of toxicity from APAP should be monitored for signs and symptoms of hepatic failure. This includes evaluating mental status and frequently assessing blood glucose. In cases in which fulminant hepatic failure develops, appropriate consultation with a hepatologist should be obtained. Transplant may be an option in severe cases.

OPIOIDS

Illicit and prescription opioids can result in a toxidrome characterized by depressed level of consciousness, respiratory depression, and miosis. However, manifestations may be variable depending on the drug used and presence of other drugs or alcohol. Miosis is not seen with meperidine, propoxyphene, and tramadol toxicity. Additional clinical findings may include hypotension, pulmonary edema, bronchospasm (heroin), ileus, nausea, vomiting, and pruritus. Seizures may be a manifestation of toxicity with meperidine, propoxyphene, and tramadol. Methadone use is associated with QT interval prolongation and ventricular arrhythmias.

Prescription opioids obtained from physicians or illicitly now account for almost 40% of all poisoning deaths in the

United States and affect all age groups.³⁴ The agents most commonly involved in deaths include methadone, oxycodone, and hydrocodone.³⁵ Toxicity depends on the potency of the agent, dose ingested, tolerance of the individual, and concomitant use of other drugs. These prescription opioids have overshadowed deaths due to heroin. Heroin is rapidly absorbed by all routes of administration including IV, intranasal, intramuscular, subcutaneous, and inhalation, but most fatal overdoses occur with IV administration. IV fentanyl (sometimes extracted from analgesic patches) is also associated with fatalities. Diagnosis of an opioid overdose is made by characteristic clinical findings, exposure history, qualitative urine toxicology assay, and response to naloxone. Qualitative urine assays may not detect all opioid derivatives (e.g., fentanyl).

The immediate priorities in a patient with opioid toxicity are support of ventilation, correction of hypotension, and reversal of the toxic effects with an opioid antagonist. If reversal of respiratory depression cannot be accomplished quickly, intubation may be necessary. Isotonic fluids should be administered for hypotension. Naloxone, a potent competitive opioid antagonist, is the antidote for opioid toxicity. It can be administered intravenously, intramuscularly, subcutaneously, by sublingual injection, or through an endotracheal tube. The initial dose of naloxone in a suspected opioid overdose is 0.04 to 2 mg; the lower dose should be considered in patients suspected of chronic addiction to avoid precipitating acute withdrawal symptoms. The goal of therapy is to restore adequate spontaneous respirations rather than complete arousal. Doses of naloxone up to 10 to 20 mg may be required to reverse the effects of synthetic opioids such as pentazocine, methadone, and fentanyl. The effects of naloxone last approximately 60 to 90 minutes, necessitating continued observation of the patient for re sedation. Patients may require continuous infusion of naloxone to maintain adequate respirations, particularly with long-acting opioids. The dose for infusion is typically one half to two thirds of the initial amount of naloxone that reversed the respiratory depression administered on an hourly basis. Adjustments of the dose should be made to achieve clinical end points and avoid withdrawal symptoms. Nalmefene, a long-acting opioid antagonist, has also been used to treat opioid overdoses, but prolonged withdrawal symptoms may be a concern.³⁶ Potential acetaminophen toxicity should be considered in patients ingesting opioids formulated with acetaminophen. Patients should also be observed for potential complications of opioid overdose including aspiration pneumonitis and noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema is usually self-limited (24 to 36 hours) and managed with supportive care that may include intubation and mechanical ventilation.³⁷ Other complications that may be related to injection drug use include wound botulism, endocarditis, rhabdomyolysis, and compartment syndrome.

SALICYLATES

Salicylates should be considered as a potential toxin if a metabolic acidosis with an anion gap of unknown cause is present. The uncoupling of mitochondrial oxidative phosphorylation by salicylates results in metabolic acidosis and hyperthermia, and the stimulation of medullary respiratory centers results in tachypnea and respiratory alkalosis. Initial

symptoms of toxicity include tinnitus and nausea or vomiting. Systemic acidosis promotes penetration of salicylate into the CNS, resulting in a depressed level of consciousness, coma, and seizures. Coagulopathy, transient hepatotoxicity, and hypoglycemia may also develop. Noncardiogenic pulmonary edema occurs more frequently in chronic salicylate toxicity than in acute overdose. The organ dysfunction and acid-base findings of salicylate intoxication can mimic sepsis and mislead clinicians.

Activated charcoal can be used for GI decontamination. Salicylates in large ingestions or enteric-coated forms can result in gastric concretions providing a depot for continued absorption; multiple doses of activated charcoal can be considered in this situation or when levels continue to rise despite other therapy.^{16,38} A salicylate ingestion is considered toxic if symptoms are present, if more than 150 mg/kg has been ingested, or if levels are higher than 35 mg/dL at 6 hours after ingestion. The Done nomogram was developed in pediatric ingestions and does not provide good clinical correlation with toxicity in adults. Acute intoxication with salicylate levels in excess of 35 mg/dL at 6 hours after ingestion should be treated with sodium bicarbonate to alkalinize the urine to a pH 7 to 8, which increases the renal clearance of salicylate metabolites through ion trapping.¹⁷ Hypokalemia will develop with correction of metabolic acidosis and must be corrected for urine alkalization to be achieved. Alkalemia shifts the gradient of movement of salicylate from brain and tissues to blood.

Fluid status must be closely monitored, along with coagulation parameters, complete blood count, ABGs, electrolytes, and urine pH. Hemodialysis may be required for levels greater than 100 mg/dL in an acute ingestion, seizures, persistent alteration in mental status, refractory acidosis, persistent electrolyte abnormalities despite adequate therapy, or fluid overload resulting from sodium bicarbonate therapy. Additional indications for hemodialysis may include congestive heart failure (relative), noncardiogenic pulmonary edema, hepatotoxicity with coagulopathy, or renal insufficiency.

CARBON MONOXIDE

Carbon monoxide (CO) poisoning may be accidental or intentional and continues to be a significant cause of morbidity in the United States. Sources of CO include motor vehicle exhaust fumes, gasoline-powered generators, poorly functioning heating systems, and inhaled smoke. CO binds to hemoglobin with an affinity 200 to 250 times greater than oxygen. Toxicities result from impaired release of oxygen at the tissue level, causing cellular hypoxia and possibly direct CO-mediated damage at the cellular level. The clinical manifestations of CO poisoning are nonspecific and may suggest other illnesses unless exposure is known or suspected. Headache, nausea, and vomiting are common. Cellular hypoxia may also result in confusion, angina, arrhythmias, syncope, and seizures. Tachycardia and tachypnea are frequently present as compensatory mechanisms for hypoxia. Classic findings of cherry red lips, cyanosis, and retinal hemorrhages occur rarely. Symptoms can range from mild to severe, and carboxyhemoglobin levels do not necessarily correlate with symptom severity. After recovery from acute CO exposure, delayed neuropsychiatric sequelae may occur.

Diagnosis requires a high level of suspicion. Carboxyhemoglobin levels can be measured in venous or arterial blood and must be interpreted carefully. Carboxyhemoglobin levels may be as high as 10% in smokers and are higher in urban compared with rural areas. An elevated level of carboxyhemoglobin may often be diagnostic, but a normal level does not rule out the diagnosis. The carboxyhemoglobin level may have decreased because of removal of the patient from the exposure and intervention with oxygen before hospital arrival.

Management of CO poisoning includes a detailed evaluation of neurologic and cardiorespiratory status. Acid-base status should be determined and an ECG examined for evidence of ischemia or arrhythmia. Oxygen is the antidote and shortens the half-life of carboxyhemoglobin by competing for binding with hemoglobin. High-concentration oxygen should be instituted as soon as possible and continued until the carboxyhemoglobin level has decreased to normal. Pulse oximetry overestimates arterial oxygenation because carboxyhemoglobin is misinterpreted as oxyhemoglobin. Analysis of arterial blood by co-oximetry is required for an accurate assessment of oxygen content. Intubation may be necessary in patients exposed to CO from fire. Hyperbaric oxygen therapy shortens the half-life of carboxyhemoglobin to 15 to 30 minutes compared with 40 to 80 minutes when patients breathe 100% oxygen. However, controversy exists over the specific indications for instituting hyperbaric oxygen therapy in CO poisoning.³⁹⁻⁴¹ Coma has been used as an indication for hyperbaric oxygen therapy; other suggested indications include a period of unconsciousness, neurologic findings other than headache, carboxyhemoglobin level greater than 40%, pregnancy with carboxyhemoglobin level greater than 15%, cardiac ischemia or arrhythmia, history of ischemic heart disease with carboxyhemoglobin level greater than 20%, and symptoms that do not resolve with normobaric oxygen after 4 to 6 hours. Hyperbaric oxygen treatment may decrease postexposure cognitive deficits.⁴²

CARDIOVASCULAR DRUGS

Cardiovascular drugs are in the top five categories of substances involved in adult overdose exposures and a leading cause of fatalities from overdose.⁴ Although a large number of cardiovascular drugs are available, the most clinically relevant agents are beta blockers, calcium channel blockers, and digoxin. Note that the clinical manifestations and management of beta-blocker and calcium channel blocker toxicity are very similar.⁴³

BETA BLOCKERS

β -Adrenergic blockers differ in their lipid solubility, oral availability, first-pass effect, protein binding, metabolism, β -1 selectivity, membrane stabilization, and intrinsic sympathomimetic activity. Clinical findings with beta-blocker toxicity include bradycardia, atrioventricular (AV) conduction abnormalities (QRS prolongation, first-degree AV block), and hypotension. The hypotension is primarily due to the negative inotropic effects of these agents. With the exception of sotalol, ventricular fibrillation and other arrhythmias are not usually seen. The more lipophilic β -adrenergic

antagonists such as propranolol, metoprolol, acebutolol, and timolol can cause delirium, coma, and seizures. Hypoglycemia is rare in adults. Toxicity generally occurs within 6 hours of ingestion of immediate-release preparations. Ingestion of sotalol or extended-release preparations may result in delayed toxicity, and these patients should be observed for 24 hours or longer if absorption is delayed. Propranolol is associated with the highest mortality rate, which may reflect its greater toxicity attributable to membrane-stabilizing effects.⁴⁴ Bradyarrhythmias and asystole usually precede death.

GI decontamination with gastric lavage may be considered if there is a large ingestion of propranolol or other more toxic agent and the patient presents within the first hour, even if symptoms are absent. Because of the risk of vagal stimulation, pretreatment with atropine may be indicated. Orogastic lavage may also be a consideration in patients with significant symptoms if the drug is suspected to still be present in the stomach. Activated charcoal is another option for GI decontamination in patients who present early after ingestion. WBI may be considered in ingestions of sustained-release preparations. Extracorporeal removal is ineffective for lipid-soluble beta blockers because of the large volume of distribution. Hemodialysis may be rarely considered for atenolol, a water-soluble beta blocker.

The primary goal of treatment is to reverse hypotension rather than to increase heart rate. Increases in heart rate do not always result in improvements in blood pressure. Although atropine is frequently administered for bradycardia, it is usually ineffective for beta-blocker and calcium channel blocker toxicity. Isotonic fluids can be administered for hypotension, but caution is warranted due to the negative inotropic effects of beta blockers on myocardial function. Pharmacologic interventions that have been used in beta-blocker overdoses include glucagon, calcium, catecholamines, insulin euglycemia therapy, and phosphodiesterase inhibitors.⁴³ IV lipid emulsion has recently been reported to be effective in refractory cases. Although clinical trials are lacking, glucagon is considered to be the appropriate initial intervention and is administered as 2 to 5 mg IV followed by a dose of 10 mg if necessary. If there is a positive clinical response, a continuous infusion (usually 2 to 10 mg/hour) is necessary owing to the short duration of action of glucagon. Glucagon is a chronotropic and inotropic agent that stimulates cyclic adenosine monophosphate (cAMP) by bypassing adrenergic receptors.⁴⁵ Adverse effects of glucagon include nausea, vomiting, hyperglycemia, and hypocalcemia.

Calcium salts should be considered as the next intervention for reversing hypotension that does not respond to glucagon if digoxin ingestion has been excluded.^{43,46} Calcium chloride 10% (1 g by slow IV push) may be administered initially, and up to 3 g is recommended. Calcium chloride is preferred over calcium gluconate because it contains three times the amount of elemental calcium. It is best administered through a central venous catheter to avoid the possibility of skin necrosis from extravasation. If access is limited, 10% calcium gluconate can be administered but an increased dose is required.

High-dose regular insulin infusions and glucose administration to maintain euglycemia have been shown to be

effective in beta-blocker and calcium channel blocker toxicity.^{46,47} The beneficial effect may be caused in part by the metabolic effects of decreasing cardiac uptake of free fatty acids and increasing carbohydrate use. Reported insulin doses have been variable, but a reasonable initial dose is 0.5 units/hour with titration based on clinical response. It is also reasonable to administer a bolus insulin dose prior to initiation of the infusion. A glucose infusion should be initiated at the same time and a glucose bolus may also be needed. Careful monitoring of glucose and potassium is required.

Catecholamine infusions are frequently administered in beta-blocker toxicity concomitantly with other interventions. No agent is known to be more effective than others and response to various agents is often inconsistent in these clinical situations. Very large doses may be required because the β -adrenergic receptors are blocked; as a result, tachyarrhythmias can occur. The combination of dobutamine and norepinephrine may allow for titration of desired effects against cardiac output and blood pressure. Alternatively, phenylephrine may be used in conjunction with dobutamine. Epinephrine has been shown to be more effective than isoproterenol.⁴⁸ Infusion of any vasoactive agent should be started at usual doses and rapidly escalated to achieve a clinical response, but it should be stopped if there is a further fall in blood pressure or no beneficial effect.

Phosphodiesterase inhibitors such as milrinone and enoximone have been reported to be effective in some cases of human ingestions.^{43,46} These agents may be useful in patients who fail other pharmacologic interventions, although experience is limited and they may cause further hypotension through peripheral vasodilation. Invasive hemodynamic monitoring may be needed in some patients.

Recent reports suggest that a bolus administration of 20% lipid emulsion (100 mL) may be beneficial in beta-blocker and calcium channel blocker cardiovascular toxicity refractory to other interventions. An additional infusion of 0.25 mL/kg/minute has been used in some cases. The exact mechanism of effect is unknown, but it has been proposed that lipids serve as a “sink” for the toxin that reduces free drug levels and limits distribution to tissues. Another possibility is that the fatty acids of lipids improve inotropy by increasing intracellular calcium concentrations.⁴⁹

Ventricular pacing (transthoracic or transvenous) may be considered, but electrical capture is often unsuccessful. Even when pacing increases the heart rate, blood pressure often fails to improve. Intra-aortic balloon pump and cardiopulmonary bypass are potential options to maintain circulation until drug is metabolized in the unstable patient unresponsive to other interventions.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers selectively inhibit calcium movement in cardiac or vascular smooth muscle membranes during the slow inward phase of excitation-contraction. These agents have varying degrees of negative inotropic effect (verapamil), vasodilatory effect (nifedipine, diltiazem), depression of rate of discharge of the sinus node (verapamil, diltiazem), and slowed conduction through the AV node (verapamil, diltiazem). All are well absorbed with clinically significant protein binding (80%) and a large

volume of distribution. All undergo extensive hepatic metabolism, many through the cytochrome P-450 system, and have varying degrees of active metabolites.

Signs and symptoms of toxicity occur within 6 hours for immediate release formulations but are delayed 6 to 18 hours for sustained-release preparations.⁵⁰ Gastric concretions often form, acting as a further reservoir for sustained absorption. Nausea, vomiting, and hypotension are usually accompanied by bradycardia with verapamil and diltiazem or reflex tachycardia with nifedipine. Conduction abnormalities associated with verapamil and diltiazem may include first-degree block, Wenckebach block, junctional rhythm, third-degree AV block, and AV dissociation. Hypoperfusion secondary to decreased cardiac output may lead to tissue ischemia and metabolic acidosis. The patient may present with CNS symptoms such as lethargy, confusion, and coma. Hyperglycemia can result from a decrease in insulin secretion and insulin resistance and may be a marker of severe exposure.

Activated charcoal is the preferred method of GI decontamination in recent ingestions. Because of the hepatic metabolism of calcium channel blockers, the parent and active metabolites exhibit enterohepatic circulation. However, once absorbed, calcium channel blockers decrease cardiac output and may lead to mesenteric ischemia and diminished bowel motility, which is a relative contraindication to MDAC. WBI may be considered for removing sustained-release preparations.

As with beta blockers, initial treatment of calcium channel blocker overdose should be aimed at treating hypotension and significant conduction defects. Interventions include the same pharmacologic interventions as for beta blockers with a change in order of administration. Calcium salts should be administered initially in toxicity due to calcium channel blockers.^{44,46} Repeat boluses of calcium may be needed every 10 minutes. If blood pressure improves with calcium, an infusion is usually needed owing to the transient effect of bolus doses of calcium. Doses up to 0.4 mL/kg/hour of 10% calcium chloride may be needed. Ionized calcium concentrations can be monitored, but high serum concentrations may be necessary for beneficial effects. Glucagon has also been reported to be beneficial in toxicity due to calcium channel blockers and it should be considered as a second intervention if there is no response to calcium.⁴⁵ Glucagon is dosed as in beta-blocker overdoses. A continuous infusion of glucagon can be titrated to maintain blood pressure, cardiac output, and sinus rhythm. Insulin-glucose infusions have also been evaluated as an adjunctive treatment in severe cases and should be considered if calcium and glucagon are ineffective.⁴⁷ As with beta-blocker overdose, large doses of catecholamines may be required. Administration of lipid emulsion can be considered in refractory cases.⁴⁹ Transthoracic or transvenous pacing may be considered but are often ineffective. Refractory hypotension may require intra-aortic balloon pump or cardiopulmonary bypass.

DIGOXIN

Cardiac glycosides inhibit active transport of Na^+ and K^+ across cell membranes by reversibly binding to a specific site on the Na^+/K^+ -ATPase. The alterations in cardiac rate and

rhythm occurring in digitalis toxicity can produce almost every type of arrhythmia. Toxicity results from the complex influence of digitalis on the electrophysiologic properties of the heart, as well as the cumulative result of the direct, vagotonic, and antiadrenergic actions of digitalis. Toxicity should be suspected if there is evidence of increased automaticity (ectopic rhythms) or depressed conduction (prolonged PR interval, AV node blockade, decreased QT interval). Early in acute intoxication, depression of sinoatrial (SA) or AV node function may be reversed by atropine, but atropine subsequently does not reverse the direct and vagomimetic actions of the drug. Noncardiac manifestations of acute digitalis intoxication include anorexia, confusion, nausea or vomiting, and increased K^+ concentrations.

GI decontamination in digoxin overdose consists of activated charcoal, if the timing is appropriate. Late administration of activated charcoal or MDAC may be considered due to enterohepatic metabolism of the drug.¹⁶ Steroid-binding resins such as cholestyramine and colestipol have also been used to prevent further absorption from the GI tract and reduce serum half-life in the same manner as charcoal. Forced diuresis, hemoperfusion, and hemodialysis are not effective in hastening the elimination of digoxin because of the large volume of distribution (4 to 10 L/kg). Only 1% of total body stores of digoxin is present in the serum; of that, 25% is protein bound.

The treatment for life-threatening digitalis toxicity is administration of digoxin-specific antibody fragments.⁵¹ Administration of digoxin-specific antibody fragments results in a sharp decrease in free digoxin levels, an increase in total serum digoxin, an increase in renal excretion of digoxin bound to Fab, and a decrease of serum potassium toward normal. The time to response is approximately 30 minutes (range 20 to 90 minutes). Indications for administration of digoxin-specific antibody fragments include severe ventricular arrhythmias, progressive bradyarrhythmias unresponsive to atropine, potassium concentration greater than 5 mEq/L in the setting of suspected digoxin toxicity, rapidly progressive cardiac or GI symptoms, an increasing potassium concentration, serum digoxin concentration greater than 15 ng/mL at any time or more than 10 ng/mL at steady state, ingestion of more than 10 mg of digoxin in a previously healthy adult, and to establish the diagnosis. In the event that digoxin-specific fragments are not immediately available, phenytoin (50 mg/minute up to 1000 mg) or lidocaine may be administered until control of the arrhythmia is achieved. Atropine may work for severe supraventricular bradyarrhythmias or varying degrees of AV block if administered early. Beta blockers may be used for supraventricular and ventricular tachycardias. Magnesium sulfate may be an effective temporizing measure for the treatment of ventricular arrhythmias in the absence of digoxin-specific antibodies, even in the presence of hypermagnesemia. All class Ia antiarrhythmic drugs are contraindicated. Isoproterenol should be avoided because there is an increased risk of ventricular ectopy in the presence of toxic digoxin levels. Transthoracic or transvenous pacing has limited value in this setting.⁵²

Hypokalemia, hyperkalemia, and hypomagnesemia can exacerbate digitalis cardiotoxicity and should be aggressively corrected. When hyperkalemia exists with toxic digoxin levels and ECG evidence of potassium toxicity, the

serum potassium should be treated with conventional interventions if digoxin-specific Fab fragments are not immediately available. Calcium chloride, in the presence of digitalis toxicity, can theoretically be disastrous because intracellular hypercalcemia already exists. Intractable ventricular fibrillation or tachycardia may result.

After digoxin-specific antibodies have been administered, serum digoxin levels are no longer reliable because they represent free and bound digoxin. The digoxin-specific antibodies are effective even in anephric patients. In renal insufficiency, the Fab half-life is prolonged 10-fold with no change in volume of distribution. Fab concentrations remain detectable for 2 to 3 weeks. Although there is no dissociation of the complex in renal insufficiency, free digoxin levels rebound (redistribution from tissue sites) and Fab fragments leave the vascular space over 7 to 14 days.⁵³ During this time symptoms may recur and a second dose may be necessary.

CYANIDE

Inhalation or ingestion of cyanide is rare but can produce severe poisoning rapidly leading to death. A history of potential cyanide exposure is extremely important in suggesting the diagnosis because rapid cyanide assays are not available and clinical manifestations are nonspecific.⁵⁴ Cyanide exposure may occur from incomplete combustion of products containing carbon and nitrogen in fires and from industrial processes such as electroplating, metal refining, photography, fumigation, and gold or silver extraction. Cyanogenic substances are also found in a variety of plants, although severe toxicity is rare. Iatrogenic cyanide intoxication may occur during nitroprusside administration with high doses or in the presence of hepatic dysfunction.

Cyanide is a nonspecific inhibitor of enzymes; inhibition of mitochondrial cytochrome oxidase results in anaerobic metabolism with decreased adenosine triphosphate (ATP) production, lactic acidosis, and decreased oxygen utilization. Clinical characteristics of acute cyanide poisoning are rapid deterioration, loss of consciousness, anion gap metabolic acidosis, and cardiopulmonary failure. CNS signs and symptoms include headache, anxiety, agitation, confusion, seizures, and coma. Cardiovascular responses manifest as initial bradycardia and hypertension, followed by hypotension with reflex tachycardia that can progress to terminal bradycardia and hypotension. Ventricular arrhythmias and myocardial ischemia also occur. Pulmonary findings include cardiogenic and noncardiogenic pulmonary edema. GI symptoms of abdominal pain, nausea, and vomiting are less common. A bitter almond odor from vomitus or gastric contents is described in cyanide poisonings but may not be present and is often not detectable by health care personnel.

Early diagnosis, rapid administration of antidote, and aggressive supportive care are necessary to stabilize patients with severe cyanide poisoning. A cyanide level may be requested for confirmation, but results will not be available to guide immediate care. Intubation and mechanical ventilation are usually required. Fluids, inotropes, and vasopressors may be indicated for hypotension. If the poison was ingested, gastric lavage may be indicated but should not delay the administration of antidote. As soon as cyanide

poisoning is suspected, a cyanide antidote kit or equivalent should be used. The kit contains amyl nitrite ampules, 3% sodium nitrite, and 25% sodium thiosulfate. Amyl nitrite is used as the first agent when lack of IV access delays the administration of sodium nitrite. It is an immediate source of nitrite that oxidizes hemoglobin to methemoglobin, which has a higher affinity for cyanide than cytochrome oxidase. Cyanmethemoglobin is formed, which eventually dissociates, but at such a rate that cyanide can be metabolized by hepatic rhodanese. The ampules are crushed in a gauze sponge and initially intermittently inhaled. This is followed by IV administration of 300 mg of sodium nitrite (10 mL 3% solution) as soon as possible. The optimum methemoglobin level that should be achieved is unknown, but clinical responses have occurred with levels of 3.6% to 9.2%. The second component of the antidote package is 25% sodium thiosulfate (12.5 g for adults), which provides sulfur for conversion of cyanide to thiocyanate by hepatic rhodanese. Thiocyanate is then excreted by the kidneys.

Hydroxocobalamin, a vitamin B₁₂ precursor administered at an initial dose of 5 g, is commonly used in Europe for acute cyanide poisoning and has been available in the United States since 2006.⁵⁵ It displaces cyanide from the cytochrome oxidase and forms cyanocobalamin, which is then excreted in the urine or metabolized by hepatic rhodanese. A second dose of 5 g can be administered for severe poisoning or lack of clinical response. Thiosulfate is administered with hydroxocobalamin. Hyperbaric oxygen has also been proposed for treating cyanide toxicity, but data supporting efficacy are not available.

DIETARY AND NUTRITIONAL AGENTS

Dietary and nutritional products are categorized as supplements and can be marketed without testing for safety or efficacy. Although some herbs and supplements may have inherent toxicity, poisoning may result from product misuse, contamination of the product, or through interaction with other medications.⁵⁶⁻⁵⁸ Patients and their families should always be questioned regarding use of nutritional supplements, herbal preparations, energy drinks, or natural remedies when considering possible toxin exposure as a cause of clinical abnormalities. Adverse effects resulting from these products should be reported to the U.S. Food and Drug Administration. Table 68.5 contains a partial list of toxicities that may result in or complicate critical illness.

Herbal teas may contain aconitine or digoxin-like substances.⁵⁹ Management is usually supportive. A digoxin level should be obtained in any patient demonstrating symptoms consistent with digoxin toxicity. The level may not correlate with clinical findings because numerous cardiac glycosides will not cross-react in the digoxin immunoassay. With significant toxicity, digoxin-specific antibodies should be administered.

Products containing ephedrine and ephedrine-free products are often used for weight loss. These products can result in manifestations similar to a sympathomimetic syndrome with cardiovascular and cerebrovascular complications.⁶⁰⁻⁶² Similarly, caffeinated energy drinks can precipitate atrial and ventricular arrhythmias.⁶³

Toxicity from ingestion of herbal preparations and nutritional supplements may result from product contaminants.

Table 68.5 Toxicities of Selected Dietary and Nutritional Agents

Agent	Toxic Effect(s)
Herbal teas	
Aconitine	Bradycardia, ventricular tachycardia and fibrillation, hypersalivation, GI disturbances, muscle weakness
Cardiac glycosides (digoxin-like factors)	Arrhythmias, GI disturbances, visual disturbances
Energy drinks (caffeine, xanthine alkaloids)	Arrhythmias, cardiac arrest
Weight loss products	
Ephedrine (ma huang)	Sympathomimetic syndrome, intracranial hemorrhage, seizures, arrhythmias, myocardial infarction, stroke, hepatic failure, rhabdomyolysis, death
Ephedrine-free supplements (bitter orange, synephrine, octopamine)	Myocardial ischemia, syncope, stroke, ischemic colitis
Ginkgo biloba	Bleeding (cerebral or extracerebral)
Ginseng	Hypoglycemia, potential bleeding
Garlic	Bleeding
Kava kava	Hepatic failure, potentiation of anesthetics

GI, gastrointestinal.

Products may contain heavy metals, unlisted drugs, or other ingredients.⁶⁴ The California Department of Health Services, Food and Drug Branch, screened 260 Asian patent medicine products and found 32% contained undeclared pharmaceuticals or heavy metals.⁶⁵ Unusual symptoms or toxidromes in patients ingesting such products may require the assistance of the local health department or toxicologist to identify a possible toxin. Additional information about specific agents can be found at www.herbmed.org or www.mskcc.org/aboutherbs.

METHEMOGLOBIN INDUCERS

Methemoglobin results from the oxidation of ferrous iron in hemoglobin to ferric iron. Methemoglobin is not able to bind oxygen and high concentrations lead to a functional anemia which results in cellular hypoxia by limiting oxygen delivery. The most common inducers of methemoglobin in the health care setting are topical spray anesthetics (benzocaine, tetracaine, butyl aminobenzoate) and dapsone. Procedures utilizing topical anesthetics that are associated with the development of methemoglobinemia are transesophageal echocardiography, GI endoscopy, intubation, and bronchoscopy.^{66,67} Predisposing factors include sepsis, anemia, and hospitalization. Dapsone may cause prolonged methemoglobinemia in patients with acquired immunodeficiency syndrome (AIDS) because of its long half-life.

Clinical manifestations are related to the impaired oxygen delivery, and the severity varies with the concentration. Cyanosis is apparent when methemoglobin concentrations are 10% or greater due to the deep color of methemoglobin. Concentrations of 20% to 50% may cause headache, dyspnea, dizziness, and fatigue and concentrations greater than 50% can result in metabolic acidosis, arrhythmias, tachypnea, seizures, lethargy, and depressed level of consciousness. Diagnosis requires measurement of methemoglobin concentrations in arterial or venous blood gas assays by co-oximetry. Pulse oximetry is not usually accurate for determining the presence or concentration of methemoglobin depending on the specific characteristics of the monitor. A helpful clue is the observance of a saturation gap between the measured oxyhemoglobin saturation by pulse oximeter and the calculated oxyhemoglobin saturation provided by ABG assay. In the presence of methemoglobin, the calculated concentration will be higher than the measured saturation by pulse oximeter. Co-oximetry is required to identify the abnormal hemoglobin.

Methylene blue is the antidote for methemoglobinemia and should be administered when there are significant symptoms indicating impaired oxygen delivery.⁶⁸ In addition, individuals with lower methemoglobin concentrations may also warrant treatment if further oxidant stress may increase the concentrations. High-flow oxygen should be administered. The usual dose of methylene blue is 1 to 2 mg/kg IV over 5 minutes. Clinical improvement in symptoms and cyanosis is usually evident within a few minutes. A second dose can be administered if cyanosis does not resolve within 1 hour. Although there is concern for methylene blue causing hemolysis in patients with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency, this information will not usually be known at the time of treatment and methylene blue should not be withheld in symptomatic patients.

ORGANOPHOSPHATE AND CARBAMATE AGENTS

Organophosphates and carbamates are cholinesterase inhibitors and are usually a component of insecticides. However, nerve agents used in chemical warfare such as sarin and VX are also organophosphate compounds. Cholinesterase inhibitors exert toxicity by blocking the activity of acetylcholinesterase resulting in acetylcholine accumulation at cholinergic receptors. When organophosphates or carbamates bind to acetylcholinesterase, they form a conjugate that is infinitely more stable than the acetylcholine-acetylcholinesterase conjugate. The carbamate-acetylcholinesterase bond spontaneously hydrolyzes in minutes to hours so that acetylcholinesterase is eventually regenerated (reversible binding). Carbamates do not penetrate the CNS based on clinical symptoms and autopsy studies.⁶⁹ Most carbamate poisonings spontaneously resolve within 24 to 48 hours and do not have significant morbidity or mortality risk. Phosphorylated or phosphonylated enzymes, however, degrade over days to weeks, making acetylcholinesterase essentially inactive (irreversible binding). For the physiologic enzyme activity to return, new enzyme must be generated or antidote given. After the acetylcholinesterase is phosphorylated over 24 to 48 hours, “aging” occurs, and the

Table 68.6 Signs and Symptoms of Cholinesterase Poisoning

Muscarinic Effects	Nicotinic Effects	CNS Effects
Salivation	Muscle	Restlessness
Lacrimation	fasciculations,	Headache
Urination	cramping,	Tremor
Diarrhea	weakness	Drowsiness
Nausea, vomiting	Diaphragmatic	Confusion,
Bronchorrhea	fatigue	delirium
Bronchoconstriction	Respiratory	Slurred speech
Miosis	failure	Ataxia
Bradycardia	Areflexia	Seizures
	Paralysis	Psychosis
	Tachycardia	Respiratory
	Mydriasis	depression

CNS, central nervous system.

enzyme can no longer spontaneously hydrolyze and is permanently inactivated.⁷⁰

Organophosphates may be absorbed by virtually any route including transdermal, transconjunctival, inhalation, across the GI or genitourinary mucosa, and through direct injection. Onset of systemic symptoms may occur in 5 minutes with inhalation, and most patients will develop symptoms within 12 hours of ingestion, unless exposure to fat-soluble organophosphates (e.g., fenthion, clorfenfion) has occurred or if significant metabolic activation must occur (e.g., parathion, malathion). Signs and symptoms of cholinesterase poisoning are listed in Table 68.6. Pulmonary toxicity from bronchorrhea, bronchospasm, and respiratory depression is the primary concern.⁷¹

Early intubation is usually indicated with significant toxicity, and succinylcholine should be avoided because of prolonged paralysis. Initially, atropine 2 to 4 mg is given IV and repeated every 5 minutes. If there are no CNS symptoms, glycopyrrolate may be substituted. The end point of atropinization is clearing of secretions. Tachycardia is not a contraindication to atropine use because it may represent hypoxia and autonomic stimulation. The tachycardia may resolve with improved oxygenation. In massive exposures, hundreds of milligrams of atropine may be required over days or weeks. A continuous infusion of atropine should be initiated at 0.05 mg/kg/hour and titrated to effect. After the patient is adequately stabilized, atropine must be carefully and slowly withdrawn because secretions will likely return if the drug is still bound to acetylcholinesterase or leaches from fat stores.

Atropine does not reverse nicotinic effects, and patients with significant respiratory muscle weakness require the use of pralidoxime. Pralidoxime is a nucleophilic oxime that regenerates acetylcholinesterase at muscarinic, nicotinic, and CNS sites. It may also prevent continued toxicity by scavenging the remaining organophosphate molecules. Treatment with pralidoxime may be most effective when started early. It may have benefit beyond the 48-hour aging limit, although the mechanisms have not been clearly

elucidated. It should be continued as long as atropine is continued. The evidence for benefit of any oxime in pesticide poisoning is limited.⁷² Pralidoxime is usually administered as a loading dose (1 to 2 g in normal saline 500 mL administered over 30 minutes) and then as a continuous infusion at 200 to 500 mg/hour to maintain serum levels higher than 4 µg/L.⁷³ Other dosing regimens have also been proposed.⁷¹ Pralidoxime may also be protective against the development of the intermediate syndrome and other long-term neurologic sequelae. Pralidoxime therapy is usually not needed if the toxin is known to be a carbamate.

In addition to acute toxicity, organophosphates may cause persistent effects, which may manifest while the patient is in the ICU and last several weeks to months. These include organophosphate-induced delayed neurotoxicity and delayed polyneuropathy that occur 1 to 3 weeks after exposure.⁷⁴ Recovery may occur gradually or not at all. The third complication is intermediate syndrome.⁷⁵ The syndrome develops 24 to 96 hours after resolution of an acute, severe cholinergic crisis, and patients develop acute respiratory paralysis, weakness in the bulbar musculature, nuchal weakness, proximal limb weakness, and depressed reflexes. Electromyography studies show decremental conduction with repetitive nerve stimulation and suggest both presynaptic and postsynaptic nerve impairment. Recovery takes 2 to 4 times longer than the development.

PSYCHOTROPIC DRUGS

CYCLIC ANTIDEPRESSANTS

Deaths caused by overdose with cyclic antidepressants are declining because of the increasing use of alternative antidepressants.⁴ The principal toxicities of cyclic antidepressants result from central and peripheral anticholinergic activity, α -adrenergic antagonism, and inhibition of norepinephrine reuptake. They also exert a membrane-depressant local anesthetic effect on the myocardium by blocking rapid sodium influx during phase 0 of the action potential. Primary toxicities include depressed level of consciousness, wide-complex arrhythmias, seizures, and hypotension. Acidosis, hypoxia, and seizures may increase the risk of wide-complex arrhythmias. Anticholinergic effects include mydriasis, fever, dry skin, delirium, agitation, tachycardia, ileus, and urinary retention. Life-threatening events usually occur within 6 hours of ingestion, most often in the first 2 hours.⁷⁶ Several electrocardiographic criteria have been proposed to predict complications: QRS duration greater than 0.1 second correlates with risk of seizures, QRS duration greater than 0.16 second correlates with increased risk of arrhythmias, and the presence of an R wave in lead aVR greater than 3 mm predicts seizures and arrhythmias.^{77,78} However, the performance of these criteria in predicting complications including death is relatively poor.⁷⁹

If poisoning with a cyclic antidepressant is suspected, electrocardiographic monitoring should be instituted and IV access obtained. Intubation may be needed in patients with CNS depression who are unable to protect their airway. If wide-complex arrhythmias (or ECG changes described previously), hypotension, or seizures are present, stabilization requires immediate alkalinization of the blood and

sodium loading with sodium bicarbonate.⁸⁰ Sodium bicarbonate should be administered in 50 to 100 mEq (1 to 2 mEq/kg) boluses to alkalinize the blood pH to 7.5 to 7.55. Clinical end points are normalization (narrowing) of the QRS complex, reestablishment of an adequate blood pressure, and termination of seizure activity. Alkalinization appears to decrease the free drug by increasing protein binding and shifting the concentration gradient away from tissues back into the main compartment. Sodium loading may have a greater benefit by overcoming the blockade of the myocardial sodium channels. The bolus doses of sodium bicarbonate should be immediately followed with a continuous infusion, which can be prepared by adding 150 mEq NaHCO₃ (sodium bicarbonate) to 1 L of D₅W. This should be titrated to the desired blood pH, QRS interval, and blood pressure. The infusion may be discontinued after 4 to 6 hours if the width of the QRS complex remains less than 100 ms without the administration of sodium bicarbonate. Hyperventilation to achieve blood alkalinization may be less effective but useful in patients who cannot tolerate the sodium and volume load or in those who develop pulmonary edema from treatment with sodium bicarbonate.^{80,81} Hyperventilation without the administration of sodium bicarbonate may also be considered for patients with cerebral edema, head trauma, or poorly controlled congestive heart failure. Hypertonic saline has been effective in treating cardiac toxicity refractory to initial blood alkalinization.^{82,83}

If torsades de pointes is associated with QT prolongation, magnesium sulfate 1 to 2 g IV over 2 to 5 minutes should be administered.⁸⁰ Hypotension refractory to volume expansion is best treated with a direct-acting catecholamine such as norepinephrine or phenylephrine in the setting of depleted norepinephrine stores.⁸⁴ An inotropic agent such as dobutamine can be added if hypotension is the result of depressed myocardial contractility and decreased cardiac output. If hypotension remains refractory to fluids and vasopressors, the use of an intra-aortic balloon pump may be considered as a temporizing measure. Recently, IV lipid emulsion has been reported to successfully treat hemodynamic instability associated with cyclic antidepressant toxicity.^{49,85}

After the patient with a known or suspected cyclic antidepressant overdose has been stabilized and the airway protected, activated charcoal is indicated. Gastric lavage should only be performed if the patient is seriously ill and the ingestion occurred within 1 hour of presentation. A second dose of activated charcoal may be given in several hours if it seems plausible that the drug still remains in the GI tract in the case of a massive ingestion or hypotension. MDAC to enhance elimination is not warranted given the extremely large volume of distribution (10 to 50 L/kg) and the low-protein binding of cyclic antidepressants.¹⁶ Forced diuresis, hemodialysis, and hemoperfusion are ineffective. Physostigmine should also be avoided because of the potential anticholinergic toxicity of seizures and asystole.

If the patient has had altered mental status, seizures, or cardiac arrhythmia, the patient should remain in the ICU for 12 hours after all supportive therapeutic interventions have been discontinued. If the patient remains asymptomatic with a normal ECG during this phase of observation, the patient may then be transferred for additional care.

LITHIUM

Although lithium is used to treat bipolar affective disorder and other psychiatric disorders, its narrow therapeutic index predisposes to toxicity.⁸⁶ After oral ingestion, lithium is absorbed within 1 to 2 hours, reaching peak blood levels in 2 to 4 hours with regular preparations or in 4 to 12 hours with sustained-release preparations. Lithium does not bind to plasma proteins and is excreted almost entirely by the kidneys. Toxicity may occur with acute, acute on chronic, or chronic ingestions. Drugs that increase lithium reabsorption (angiotensin-converting enzyme [ACE] inhibitors, thiazides, nonsteroidal anti-inflammatory drugs), sodium restriction, volume depletion, and intrinsic renal dysfunction increase the risk of toxicity. Lithium levels do not necessarily correlate with toxic symptoms. With an acute ingestion, the patient may be asymptomatic with a lithium level of 6 to 8 mmol/L. In chronic lithium ingestion, a high total-body lithium burden results in more immediate toxicity at lower serum levels.

The clinical presentation of patients with lithium toxicity varies with the type of ingestion. In an acute ingestion, nausea, vomiting, and diarrhea occur early with CNS symptoms developing later because of a delay in tissue distribution. In chronic ingestions, neurologic abnormalities are usually the major presenting manifestations. Patients with acute on chronic ingestions may manifest GI and neurologic symptoms. Neurologic abnormalities include tremor, hyperreflexia, agitation, fasciculations, clonus, and altered mental status. Confusion may be followed by lethargy, coma, and seizures. The tremor, hyperreflexia, and clonus usually precede altered mental status. Lithium can impair urine-concentrating ability in acute ingestions and cause nephrogenic diabetes insipidus and renal dysfunction in chronic ingestions that result in volume depletion. Although myocardial dysfunction and rhythm abnormalities have been reported in lithium toxicity, they occur infrequently. Lithium toxicity may produce flattened or inverted T waves and U waves on ECG.

Lithium toxicity is confirmed by assessment of the serum lithium level. A lithium level should be assessed immediately and 2 hours later to evaluate for increasing levels. Levels higher than 2.5 mmol/L in a chronic ingestion or higher than 4 mmol/L in an acute ingestion are potentially life-threatening. Renal function and volume status should also be assessed.

Management decisions in treating lithium toxicity may depend on the type of ingestion (acute versus chronic) and the product ingested (regular versus sustained-release). Lithium is not adsorbed by activated charcoal, but charcoal may be administered if other drugs are ingested or suspected. A forced diuresis is not effective in enhancing lithium excretion, but isotonic saline should be administered to replete and maintain intravascular volume and promote adequate urine output.⁸⁷ Diuretics can worsen lithium toxicity and should be avoided. WBI has been proposed for GI decontamination with acute or acute on chronic ingestions, ingestion of sustained-release products, or when serial lithium levels are rising. Despite lack of proven clinical benefit, this approach may be considered with appropriate precautions. Hemodialysis is effective in removing lithium, but controversy exists on the indications

for treatment and duration of therapy. Proposed indications that have not been validated include renal dysfunction, severe neurologic dysfunction, inability to tolerate fluid replacement, lithium level higher than 4 mmol/L in an acute overdose, and lithium level higher than 2.5 mmol/L in chronic toxicity. The lithium level, duration of exposure, and severity of clinical symptoms should be balanced against risks of the procedure before initiating hemodialysis. Hemodialysis clears lithium only from the plasma, and a rebound increase can develop from drug redistribution. A lithium level should be assessed immediately after hemodialysis and 6 to 8 hours later. Repeat dialysis can be considered if the lithium level increases or neurologic toxicity persists at that time. Although a lithium level of 1 mmol/L is often recommended as the end point for hemodialysis, no systematic investigations have established the ideal end point for optimal outcome. Because of redistribution of lithium, improvement of neurologic toxicity lags behind the decrease in plasma level. Prolonged monitoring of lithium levels may be necessary, especially when sustained-release preparations are ingested. Continuous venovenous hemodiafiltration has also been used to remove lithium and may be associated with less rebound.⁸⁸ This technique results in a slower lithium clearance compared with hemodialysis and is not recommended if hemodialysis is available and can be tolerated. Sodium polystyrene sulfonate resin has been proposed to bind and remove lithium, but it is not currently recommended and may result in hypokalemia, hypernatremia, and fluid overload. Aminophylline and low-dose dopamine infusions have also been proposed to enhance lithium excretion, but no evidence of clinical efficacy exists and they should not be used.⁸⁷

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selective serotonin reuptake inhibitors (SSRIs) and related antidepressants are frequently prescribed for depression and other disorders. They have decreased lethality and fewer adverse cardiovascular effects compared with cyclic antidepressants.⁸⁹ Most fatalities involving SSRIs involve coingestion of other substances. Manifestations of an acute SSRI overdose may include nausea, vomiting, dizziness, blurred vision, and rarely CNS depression. Seizures and a wide QRS occur rarely but may be more likely with citalopram and bupropion, a unicyclic antidepressant. A syndrome characteristic of SSRIs is the serotonin syndrome, which may occur after a single dose, high dose, overdose, or when combined with other serotonergic agents.⁹⁰ The pathophysiology is related to excessive stimulation of central and peripheral serotonergic receptors. Clinical manifestations include altered mental status ranging from agitation to coma; autonomic dysfunction including diaphoresis, tachycardia, hyperthermia, unstable blood pressure, and diarrhea; and neuromuscular abnormalities that may range from tremors to myoclonus and rigidity.⁹¹ Severe cases may be complicated by rhabdomyolysis, renal failure, disseminated intravascular coagulation, or acute respiratory distress syndrome.

Management of an acute overdose of SSRIs is largely supportive. Gastric lavage is not warranted because of the low toxicity of these compounds, but use of activated charcoal may be considered. An ECG should be obtained to assess for the rare occurrence of a wide QRS complex or other

electrocardiographic abnormality. Although clinical experience is limited, there are reports of sodium bicarbonate administration resulting in narrowing of the QRS complex. The treatment of serotonin syndrome is primarily supportive therapy after discontinuing the precipitating agents. Intubation and mechanical ventilation may be necessary for patients with significant alteration of mental status. Benzodiazepines are useful for control of agitation and external cooling for sustained hyperthermia. Rarely, neuromuscular blockers may be necessary for control of muscle rigidity or tremor. The syndrome usually resolves in 24 to 72 hours. Treatment of patients with serotonin antagonists has been proposed, but experience is limited to case reports. Cyproheptadine in varying dose regimens (12 to 32 mg/24 hour) has been most commonly recommended as a treatment option. Currently there is no role for the use of bromocriptine or dantrolene.⁹¹

SEDATIVES

BENZODIAZEPINES

Although ingestions are relatively common, fatalities from benzodiazepines alone are uncommon. Benzodiazepine overdose results in a typical sedative-hypnotic toxidrome characterized by depressed level of consciousness, respiratory depression, hyporeflexia, and potentially hypotension and bradycardia. The clinical manifestations may be exacerbated by concomitant ingestion of other agents with sedating properties, such as ethanol, opioids, or antidepressants. Alprazolam is commonly seen in overdoses due to wide availability and may result in greater toxicity than other benzodiazepines.⁹² Flunitrazepam is a benzodiazepine not approved for use in the United States that has been associated with sexual assault. Diagnosis of benzodiazepine ingestion is primarily based on the history and clinical manifestations. Many benzodiazepines can be detected in qualitative urine toxicology assays, but a negative test does not rule out ingestion. If warranted, gas chromatography/mass spectrometry can be requested for definitive detection.

Managing benzodiazepine ingestions should be guided by the clinical presentation of the patient. The airway is assessed and stabilized if necessary. Activated charcoal is the primary method of GI decontamination for recent ingestions. Supportive care with intubation and mechanical ventilation may be necessary for patients with significant toxicity. Hypotension usually responds to volume infusion.

Flumazenil is a competitive benzodiazepine receptor antagonist that will reverse the sedative effects of benzodiazepines. It may be a helpful diagnostic tool in evaluating an overdose patient but should not be routinely used as a substitute for adequate airway protection.⁹³ A dose greater than 1 mg is seldom necessary in overdose victims. The short half-life of flumazenil (0.7 to 1.3 hours) makes re-sedation likely because of the longer half-life of benzodiazepines. Continuous monitoring must be instituted if flumazenil is used to arouse the patient. Flumazenil use has been associated with seizures in patients with chronic benzodiazepine use and when cyclic antidepressants are present.⁹³ It is best to avoid flumazenil in those situations and in patients with a seizure disorder or when a drug capable of causing seizures has been ingested. Slow titration

of flumazenil (0.1 mg/minute) and limiting the total dose to 1 mg may minimize the risk of seizures. If seizures occur with flumazenil, benzodiazepines (often in higher doses) may be effective.

GAMMA HYDROXYBUTYRATE

Gamma hydroxybutyrate (GHB), a naturally occurring substance found in the brain and peripheral tissues, is banned in the United States except for the treatment for narcolepsy. It is one of several agents characterized as a “date rape” drug and has been promoted to build muscle, improve performance, produce euphoria, induce fat loss, and enhance sleep. Several deaths have been attributed to GHB and related agents.⁹⁴ The drug is usually available as a colorless, odorless liquid with a mild, salty taste that is easy to mask in drinks. GHB is rapidly absorbed from the stomach (usually within 10 to 15 minutes) and readily crosses the blood-brain barrier. It is metabolized to carbon dioxide and water without active metabolites. Stimulatory effects occur from resulting increased dopamine levels in the brain and sedative effects by potentiation of endogenous opioids. The manifestations of GHB toxicity are dose related and include agitation, coma, seizures, respiratory depression, and vomiting.⁹⁵ Other effects include amnesia, tremors, myoclonus, hypotonia, hypothermia, decreased cardiac output, and bradycardia. Coma and respiratory depression may be potentiated by the concomitant use of ethanol. GHB is not routinely detected by urine toxicology assays but can be detected in plasma or urine by gas chromatographic and mass spectrophotometric techniques. Diagnosis is usually determined by the clinical course and history of exposure elicited after the patient recovers. Gamma butyrolactone (GBL), also known as 2(3H)-furanone dihydro, and 1,4-butanediol (BD), also called tetramethylene glycol, have been abused with the same adverse effects as GHB including death. Both agents are metabolized in the body to GHB.⁹⁴

No antidote for GHB, GBL, or BD exists. The primary management for ingestion of these drugs is supportive care with particular attention to airway protection and ventilation. In some cases, intubation and mechanical ventilation are required. Gastric lavage and activated charcoal are not indicated because of the small amounts involved and the rapid absorption. Naloxone and flumazenil are of no benefit. Patients with mild intoxication may be observed in the emergency department and released after symptoms resolve. A rapid recovery of consciousness from an obtunded condition is frequently observed. In patients requiring intubation and mechanical ventilation, symptoms can be expected to resolve within 2 to 96 hours unless complications such as aspiration or anoxic injury have occurred. The concomitant use of alcohol may prolong the CNS depression. Although physostigmine has been used to awaken patients with GHB intoxication, its use is not recommended.⁹⁶

A withdrawal syndrome has been described in patients who frequently ingest high doses of GHB (every 1 to 3 hours).⁹⁷ Mild symptoms such as anxiety, insomnia, nausea, vomiting, and tremors begin within 6 hours of the last dose and may progress to severe delirium with autonomic instability (usually mild) requiring hospitalization and sedation. The duration of symptoms requiring treatment may be as long as 2 weeks. Benzodiazepines are the initial choice for

management, and high doses may be required. Propofol and barbiturates have also been used successfully.

PROPOFOL

Propofol is a sedative-hypnotic used for general anesthesia, procedural sedation, more prolonged sedation in critically ill patients, and treatment of status epilepticus. It has also been implicated in abuse, accidental overdose, suicide, and even murder.⁹⁸ The critical care clinician should be aware of a potentially fatal toxicity associated with more prolonged infusions of propofol known as propofol-related infusion syndrome (PRIS).⁹⁹ The syndrome is usually associated with doses of propofol greater than 4 mg/kg/hour for longer than 48 hours' duration. However, metabolic acidosis has been reported within 1 to 4 hours after the initiation of propofol infusion. Predisposing factors that have been associated with PRIS include young age, CNS or respiratory illness, vasopressor use, glucocorticoid use, greater severity of illness, sepsis, and impaired oxygen delivery. Mortality rates of 18% to 80% have been reported.⁹⁹ Clinical features of the syndrome can include refractory bradycardia progressing to asystole, other arrhythmias, myocardial failure, lactic acidosis, rhabdomyolysis, renal failure, and hypertriglyceridemia.¹⁰⁰ The pathophysiology is hypothesized to be related to mitochondrial utilization of free fatty acids and genetic predisposition.

Propofol infusions should be limited to less than 4 mg/kg/hour and no longer than 48 hours of infusion when possible. Prompt recognition of early signs of PRIS (elevated serum lactate, elevated creatine kinase, hypertriglyceridemia) is essential for successful intervention. Another clinical clue to possible PRIS is the unexplained need for increasing doses of pressor or inotropic agents. Management includes discontinuation of propofol and the use of alternative sedative agents. The most effective treatment for severe PRIS is cardiorespiratory support and hemodialysis or hemofiltration to decrease blood levels of metabolic acids and lipids.¹⁰⁰

STIMULANTS

AMPHETAMINES/METHAMPHETAMINES

Amphetamines, methamphetamines, and related agents cause central and peripheral release of catecholamines, which result in a sympathomimetic/adrenergic toxidrome characterized by tachycardia, hyperthermia, diaphoresis, agitation, hypertension, and mydriasis. Hallucinations (visual and tactile) and acute psychoses are frequently observed. The clinical manifestations associated with abuse of these agents may last up to 24 hours due to the longer duration of pharmacologic effects. The acute adverse consequences are similar to those seen with cocaine abuse (see following) and include myocardial ischemia and arrhythmias, pulmonary hypertension, seizures, intracranial hemorrhage, stroke, hepatotoxicity, rhabdomyolysis, necrotizing vasculitis, and death.¹⁰¹ Chronic use of these drugs may result in dilated cardiomyopathy.¹⁰² Poor oral hygiene and severe dental caries ("meth mouth") can be clues to chronic methamphetamine use.¹⁰³

Methamphetamine hydrochloride in a crystalline form called "ice," "crank," or "crystal" is one of the most popular drugs in this class. It has high purity and can be orally ingested, smoked, insufflated nasally, or injected

intravenously. An amphetamine-like drug (3,4-methylenedioxymethamphetamine) is a designer drug commonly known as Ecstasy, XTC, or MDMA that acts as a stimulant and hallucinogen.¹⁰⁴ It results in serotonin release in the brain with inhibition of serotonin reuptake and has been reported to produce serotonin syndrome. Complications are usually a result of the drug effects and excessive physical activity. Complications include hyperthermia, hyponatremia (excessive water intake or syndrome of inappropriate antidiuretic hormone secretion), rhabdomyolysis, renal failure, cardiac collapse, cerebral infarction/hemorrhage, and multiple organ failure. MDMA and other amphetamines will usually be detected on qualitative toxicology assays of urine but false positives and negatives occur.

Management of amphetamine intoxication is primarily supportive. Gastric lavage is not recommended because absorption after oral ingestion is usually complete when patients present. Activated charcoal may be considered if a recent oral ingestion is known to have occurred. Further interventions are dependent on patient complaints and clinical findings. A careful assessment for complications should be made including measurement of core temperature, obtaining an ECG, and evaluating laboratory data for evidence of renal dysfunction and rhabdomyolysis. IV hydration for possible rhabdomyolysis is warranted in individuals with known exertional activities pending creatine phosphokinase (CPK) results. Benzodiazepines, often in high doses, are used to control agitation. Haloperidol should be reserved for patients who do not have an adequate response to benzodiazepines. Seizures are best treated with benzodiazepines.

COCAINE

Cocaine abuse is a global problem that results in significant medical complications.¹⁰⁵ Cocaine hydrochloride is water soluble and can be injected intravenously, ingested, or snorted intranasally. Crack or rock cocaine is the alkaloid form primarily abused by inhalation. The onset, peak, and duration of physiologic effects of cocaine vary with the route of use, form of cocaine used, and concomitant use of other drugs.¹⁰⁵ Both forms of cocaine are absorbed from all mucosal surfaces and undergo hydrolysis by plasma and liver cholinesterases. The major metabolites, benzoylecgonine and ecgonine methyl ester, are excreted in the urine and can be detected by qualitative urine assays. The metabolites of cocaine may be detectable in urine for 24 to 36 hours after use, but prolonged detection can occur in frequent users of high doses.

Cocaine inhibits the presynaptic reuptake of biogenic amines such as norepinephrine, dopamine, and serotonin throughout the body including the CNS. Characteristic clinical findings of a sympathomimetic syndrome include tachycardia, mydriasis, hypertension, hyperthermia, diaphoresis, euphoria, and agitation. The sympathetic stimulation also results in multiple potential complications (Box 68.3). Complications such as myocardial ischemia or cerebral infarction may occur several days after the last use of cocaine. Complications of transporting cocaine in body cavities may include rupture of packets with drug absorption and bowel obstruction.

No specific antidote exists for cocaine. Treatment is primarily aimed at detecting complications, intervening as

Box 68.3 Complications Associated with Cocaine Use

Cardiovascular

Myocardial ischemia, infarction
Arrhythmias
Aortic dissection, rupture
Hypertension

Metabolic

Hyperthermia
Rhabdomyolysis
Weight loss
Multiple organ failure

Other

Deep venous thrombosis
Skin ischemia
Dystonic reactions

indicated, and preventing further injury. Benzodiazepines should be used liberally for control of agitation. Haloperidol is reserved for overt psychosis because of its potential for lowering the seizure threshold.

No large clinical trials have evaluated therapeutic strategies for myocardial ischemia resulting from cocaine use. Aspirin should be administered if the risk of intracranial hemorrhage is low because a significant number of patients have thrombotic occlusion as the cause of ischemia. Benzodiazepines and nitroglycerin are first-line agents for relief of chest pain, but small clinical studies have yielded conflicting results on the benefit of combining the agents.¹⁰⁶ α -Adrenergic blockers such as phentolamine and calcium channel blockers have been recommended as second-line treatment for unrelieved pain but are rarely necessary.¹⁰⁶

Beta blockers were often considered to be contraindicated in the management of potential ischemia related to cocaine because of the potential for unopposed α -adrenergic-mediated vasoconstriction leading to elevated blood pressures. However, beta-blocker use was not found to be detrimental in two retrospective studies of patients with recent cocaine use and may be beneficial in some patients.^{107,108} It may be appropriate to avoid administration of beta blockers in patients manifesting acute sympathomimetic findings. In addition, routine use of IV beta blockers is no longer recommended for acute coronary syndromes. Reperfusion interventions, primarily percutaneous coronary interventions, should be considered for patients with myocardial infarction.¹⁰⁶ Ventricular arrhythmias are not common and may be related to cocaine blockade of myocardial sodium channels leading to QRS and QT interval prolongation. Wide complex arrhythmias may respond to treatment with sodium bicarbonate.¹⁰⁹ Class IA antiarrhythmic drugs such as procainamide should be avoided. Treatment of life-threatening arrhythmias should otherwise follow advanced life support guidelines.

Cerebral complications should be managed by standard interventions specific for the injury. Seizures are best managed with benzodiazepines. The reported incidence of underlying vascular malformations in intracranial hemorrhage has been variable, but if present these problems may require specific intervention. Severe hyperthermia is managed the same as heat stroke with either conductive or evaporative cooling.¹¹⁰ When there is suspicion of rhabdomyolysis, IV hydration should be instituted immediately pending assessment of renal function and CPK levels. Asymptomatic transporters of cocaine packets should be managed conservatively with activated charcoal, possible WBI, and supportive care. Surgery is reserved for patients exhibiting manifestations of cocaine poisoning or GI perforation or obstruction.¹¹¹ Contamination of cocaine with other drugs or fillers can result in toxicities that are not directly related to the effects of cocaine. Levamisole, an anthelmintic agent used in veterinary medicine, has been found in cocaine supplies and linked to the development of agranulocytosis.¹¹² Agranulocytosis resolves when drug use is discontinued. Retiform purpura and skin necrosis secondary to thrombotic vasculopathy have also been linked to cocaine contaminated with levamisole.^{113,114} The potential for suicidal intent should be recognized in cocaine abusers, and psychiatric consultation may be appropriate after stabilization.

MEPHEDRONE/METHYLENEDIOXYPYROVALERONE (BATH SALTS)

Mephedrone and 3,4-methylenedioxypyrovalerone (MDPV) are synthetic stimulants marketed in products sold as bath salts to avoid regulation. MDPV inhibits reuptake of dopamine and norepinephrine, and mephedrone may act as a monoamine reuptake inhibitor.¹¹⁵ Street names include Ivory Wave, Bliss, White Lightning, Vanilla Sky, Hurricane Charlie, White Knight, and others. The products have been ingested, snorted, smoked, and injected and are often used in combination with alcohol or other drugs. These agents are not detected by qualitative toxicology screens.

Clinical manifestations are similar to those of other stimulant drugs and include agitation, tachycardia, hyperthermia,

hypertension, mydriasis, chest pain, palpitations, seizures, hallucinations, delusions, and paranoia.^{115,116} Symptoms may be prolonged for more than 24 hours after use of mephedrone despite a short expected half-life.¹¹⁶ Management includes IV benzodiazepines for significant agitation and psychotic symptoms. Symptoms may recur as sedation wears off, requiring repeat dosing. A thorough clinical evaluation is required to identify other complications such as rhabdomyolysis, myocardial ischemia, and organ dysfunction. Seizures are best treated with IV benzodiazepines.

VALPROIC ACID

Use of valproic acid (VPA) for seizure disorders, psychiatric disorders, migraine prophylaxis, and neuropathic pain has resulted in increased toxicity reported with therapeutic doses and overdoses. The most common manifestation of toxicity in overdoses is CNS depression with higher drug levels associated with an increased incidence of coma and respiratory depression requiring intubation.¹¹⁷ Cerebral edema may occur 48 to 72 hours after overdoses and may be related to hyperammonemia that usually occurs in the absence of hepatotoxicity. The increase in ammonia is not well understood but may be related to carnitine deficiency, renal abnormalities, or defects in the urea cycle.¹¹⁷ Large VPA ingestions can result in refractory hypotension. Pancreatitis has been associated with chronic ingestion and acute overdose. Metabolic abnormalities of VPA toxicity include hyponatremia, hyperammonemia, anion gap metabolic acidosis, hypocalcemia, and acute renal failure. Hepatotoxicity is rare with VPA overdoses, but mild, asymptomatic abnormalities may occur with chronic use.

Initial and serial VPA levels should be obtained because of delayed peak serum levels in overdose. Patients may be comatose with normal serum VPA concentrations caused by unmeasured metabolites. An ammonia level should be obtained in patients with altered level of consciousness. Activated charcoal should be administered if the patient presents early after ingestion. MDAC may be beneficial because of a potential enterohepatic recirculation of drug, but routine use is not currently recommended. Although VPA is highly protein bound, protein binding is saturated at high serum concentrations resulting in more free drug being available for removal by extracorporeal techniques. Hemoperfusion, combined hemodialysis-hemoperfusion, or high flux hemodialysis may be considered in patients with severe or persistent hemodynamic instability, coma, or metabolic acidosis.¹¹⁸ No antidote exists for VPA toxicity, but L-carnitine administration has been proposed for patients with VPA toxicity and hyperammonemia. Chronic VPA therapy has been associated with carnitine deficiency and case reports suggest that L-carnitine administration is safe.¹¹⁹ However, there is no evidence that L-carnitine alters clinical outcome and more rigorous study is needed. Dosing of L-carnitine in reports has been variable but a suggested regimen is 100 mg/kg IV bolus or infusion over 15 to 30 minutes, followed by 50 mg/kg (maximum 3 g/dose) every 8 hours until the ammonia level is decreasing and the patient clinically improves.¹¹⁹

KEY POINTS

- Evaluating and managing the poisoned patient involves resuscitation and stabilization, diagnosis, GI decontamination and toxin elimination, institution of specific antidotes or interventions, and supportive care.
- In the poisoned patient with altered mental status, hypertonic dextrose, thiamine, and naloxone should be considered for administration.
- Patterns of signs and symptoms identified by physical examination may often suggest a toxidrome that is associated with classes of toxins.
- Single-dose activated charcoal is most effective when administered within 1 hour of toxin ingestion; later administration may be appropriate if clinical factors suggest the toxin has not yet been completely absorbed.
- Recognition of potential acetaminophen toxicity is essential for appropriate treatment and prevention of morbidity.
- Findings of bradycardia and hypotension should suggest possible ingestion of a beta blocker or calcium channel blocker.
- Dietary and nutritional supplements can result in significant cardiac and cerebrovascular toxicities.
- Cyclic antidepressant toxicity with increased QRS duration or wide complex tachyarrhythmia requires immediate alkalinization of the blood with sodium bicarbonate or hyperventilation.
- The initial treatment for patients presenting with a clinical syndrome suggesting a stimulant toxin (cocaine, amphetamines, bath salts) is IV benzodiazepines for control of agitation.
- Be aware of potential toxicities that can develop in ICU patients exposed to propylene glycol-containing medications, topical anesthetics, and propofol.

HYPOTHERMIA

Cold exposure has been recognized as a cause of death since ancient times. In the year 492 BC, the Persians were sailing to launch their attack against the Greeks when they encountered bad weather and lost about 300 ships and 20,000 soldiers. Herodotus wrote, "... some were dashed by the rocks, and some of them did not know how to swim and perished for that cause, others again by reason of *cold*."

In order to recognize hypothermia, it must be possible to measure a temperature. The first thermometer for clinical use was invented in 1612. It was a foot long and required 20 minutes to register a temperature. The invention of the mercury thermometer by Fahrenheit in 1714 made the tool more practical. However, it was not until the late nineteenth century that the thermometer became a clinical tool. This use was established after the invention of a small thermometer that only required 5 minutes to obtain a temperature (1866) and after Carl Wunderlich's publication (1868), which presented data on nearly 25,000 patients and analyzed temperature variation in 32 diseases. In the early 1900s, temperature was routinely measured and physiologic

experiments started to appear. By the 1930s to 1940s, therapeutic hypothermia for malignancy and anesthesia was investigated. By the middle of the twentieth century, accidental hypothermia was established as a disease entity.¹

This section discusses the epidemiology, definition, pathophysiology, clinical diagnosis, clinical manifestations, and management of hypothermia.

EPIDEMIOLOGY

Accidental hypothermia continues to be a public health problem. The Centers for Disease Control and Prevention (CDC) reports that between 1979 and 2002, a total of 16,555 deaths in the United States (average of 689 per year, range 417-1021) were attributed to excessive natural cold.²

Approximately 50% of all hypothermia-related deaths occur in persons older than 65. The age-adjusted mortality rate is three times higher for men than it is for women. In blacks and other races, the mortality rate is higher than that of whites.^{2,3} Blacks have decreased heat production and lower rectal temperatures in response to cold exposure.⁴ Other populations at risk include the elderly, people with preexisting chronic medical conditions, and people

suffering from alcoholism and drug intoxication.^{2,3,5} Emerging populations include wilderness enthusiasts and winter sport participants.⁶

Despite advances in medical care, hypothermia remains a challenge to health care providers, with in-hospital mortality rate reaching 40%,⁷ and an overall mortality rate ranging from 17% to 80%.⁸ The prompt recognition and appropriate management play a key role in improving outcomes.

DEFINITION

Hypothermia is defined as a core body temperature lower than 35°C (<95°F). It has been further classified by severity according to the degree by which the core temperature has decreased from baseline into mild, moderate, and severe. Mild hypothermia is defined by a core body temperature of 32° to 35°C (90-95°F). Moderate hypothermia reflects a core body temperature of 28° to 32°C (82-90°F). Severe hypothermia is a core body temperature of less than 28°C (less than 82°F). Some reports refer to severe hypothermia below 30°C. In trauma patients, hypothermia carries a poorer prognosis. In this case, the definition is even more conservative, with severe hypothermia starting below 32°C. This subclassification has important implications regarding the anticipated physiologic changes and subsequently the use of appropriate therapeutic modalities.^{9,10}

HEAT REGULATION

Body temperature is regulated through a balance between heat production and heat dissipation.¹¹ Heat production occurs mostly from the metabolic activity of energy-consuming processes within the viscera, namely, the heart, liver, and brain. Heat production in these organs is estimated to be between 40 and 60 kcal/m²/hour. Normally heat production is increased by food intake and muscle activity. Different stresses such as fever, infection, and cold exposure also increase heat production.

Heat loss occurs through different forms. Radiation cooling (infrared emissions) accounts for approximately 60% of heat loss. It occurs primarily from the head and unisolated parts of the body. Conduction (direct transfer of heat to an adjacent cooler object) and convection (direct transfer of heat to convective air currents) account for around 10% to 15% of heat loss. Evaporation from the skin and respiratory tract accounts for 25% to 30%. Conduction is an important mechanism in immersion accidents because thermal conduction of water is 30 times that of air. Convection is important in windy conditions by removing the warm isolating layer of air around the body.^{6,10,11}

Upon cold exposure, the hypothalamus initiates mechanisms for heat conservation and heat production. Heat conservation is achieved by peripheral vasoconstriction, reducing heat conduction to the skin, and behavioral responses such as wearing more clothes and seeking a warmer environment. Heat production is achieved through stimulation of muscular activity via shivering, which can increase the basal metabolic rate by two to five times. A nonshivering thermogenesis occurs via increased levels of catecholamines and thyroxine.¹²

This coordinated physiologic response occurs typically for temperatures between 32° and 35°C. It only lasts for few

hours, after which muscle fatigue and glycogen depletion ensue. As the core temperature drops below 32°C (90°F), shivering thermogenesis abates, and nonshivering thermogenesis slows down. By temperatures below 20° to 24°C, the different mechanisms of heat production completely fail.¹³

CLINICAL PRESENTATION

ETIOLOGIC FACTORS (FIG. 69.1)

Factors that predispose to hypothermia are related to impaired thermoregulation, increased heat loss, and decreased heat production. A combination of these factors is often noted in a hypothermic patient.

1. *Impaired thermoregulation* is of critical importance in the elderly, mentally ill, and patients with chronic medical conditions such as Parkinson's disease, stroke, multiple sclerosis, and diabetes mellitus. Such populations are often on multiple medications including anxiolytics, antidepressants, phenothiazines, barbiturates, opioids, antipsychotics, oral antihyperglycemics, beta blockers, and alpha blockers. These drugs can cause further impairment in thermoregulation.¹⁴ In addition, the elderly and chronically ill may suffer from maladaptive behavior (decreased mobility, and inability to communicate effectively), which increases the chance of remaining in an environment with prolonged cold exposure.¹⁴
2. *Increased heat loss* can be environmental or nonenvironmental.
 - a. Hypothermia commonly occurs during winter weather and in cold climates. People with inadequate insulation and continued cold exposure are especially at risk.
 - b. Patients with dermatologic dysfunction such as burns, psoriasis, and exfoliative dermatitis can have increased heat loss.
 - c. Large amounts of unheated intravenous fluid resuscitation, whether crystalloids or blood, coupled with unheated humidified oxygen, predispose hospital and trauma patients to greater heat loss.
 - d. Conditions that cause vasodilation should be highlighted in this category and include alcohol, anesthesia, and toxins released in disease entities such as sepsis.
3. *Decreased heat production* is noted in some specific types of disorders:
 - a. Endocrine dysfunction such as hypopituitarism, hypothyroidism, hypoadrenalism, and hypoglycemia.
 - b. Malnutrition and starvation, which cause decreased insulative subcutaneous fat and are often associated with hypoglycemia.
 - c. Conditions that alter the level of consciousness, causing decreased shivering mechanism. Drugs such as phenothiazines and tricyclic antidepressants as well as alcohol can induce impairment of shivering.⁶

DIAGNOSIS

Diagnosis should be performed using a thermometer probe capable of measuring temperatures as low as 25°C (77°F). This instrument could be a rectal, esophageal, or bladder probe. It should be noted that standard clinical thermometers do not register below 34.4°C (94.4°F).¹⁵ Combined

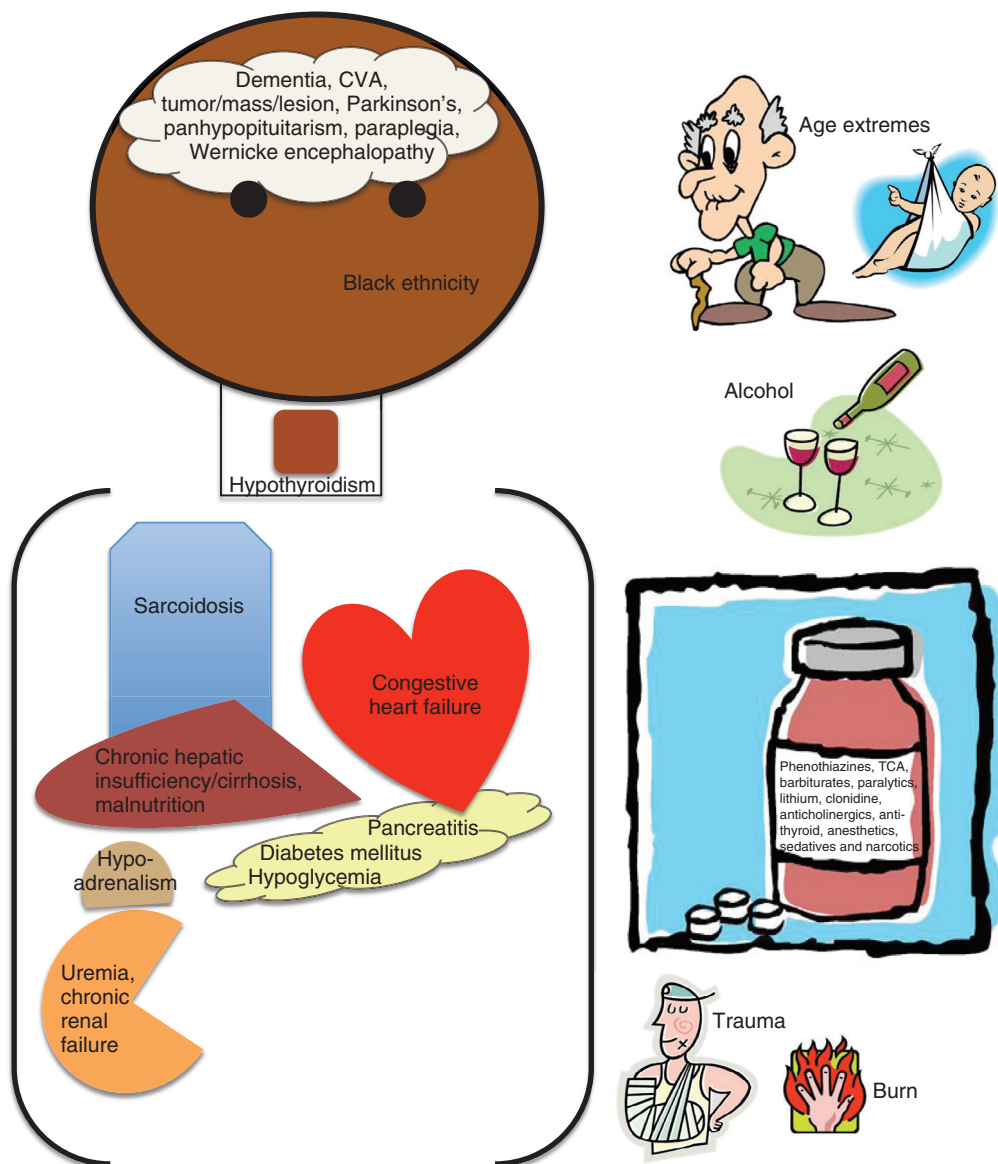

Figure 69.1 Diseases and factors associated with hypothermia.

methods for temperature monitoring may allow better detection of further changes.

END-ORGAN MANIFESTATIONS (FIG. 69.2)

Although hypothermia is divided into three stages, it is important to note that the physiologic changes follow a continuum. The initial mechanisms mimic intense sympathetic stimulation, which fades as body temperature drops. Almost every organ in the body is affected by hypothermia.¹⁶

Cerebral Effects

Hypothermia is associated with progressive decrease in neuronal metabolism between 35° C and 25° C. This protective effect of hypothermia allows better tolerance to periods of cardiocirculatory collapse in contrast with the normothermic state.^{6,17,18} Neurologic symptoms starts with mild hypothermia. Between 34° and 35° C, loss of fine motor skills, lack

of coordination, dysarthria, and amnesia take place. Ataxia and apathy are noted around 33° C.¹⁹ Below 32° C, progressive decrease in level of consciousness and pupillary dilation develops. Cerebrovascular autoregulation is lost below 25° C. Deep tendon reflexes diminish and flaccid muscular tone takes place below 27° C. By 23° C, corneal and oculocephalic reflexes are absent. The electroencephalogram (EEG) pattern flattens at 19° to 20° C. The lowest temperature reported for an adult survival with hypothermia is 13.7° C.^{6,15,20} Therefore, one has to be very careful in assessing brain death when a patient remains hypothermic.⁸

Cardiovascular Effects

The initial response (34-36° C) includes increased heart rate, blood pressure, and carbon dioxide secondary to elevated catecholamine production and peripheral vasoconstriction.⁶ This is associated with marked increase in oxygen consumption. A core temperature decrease of as little as

Figure 69.2 Hypothermia: clinical presentation and treatment approach.

0.3° C is associated with a 7% increase in oxygen consumption. The increase in oxygen requirement results in anaerobic metabolism, acidosis, and significant cardiopulmonary stress, further worsening the abnormal physiology of hypothermia.¹⁶ Below 34° C, progressive bradycardia and decrease in cardiac output and blood pressure take place. Below 28° C, 50% of patients show bradycardia with a 50% decrease in heart rate. Bradycardia is chiefly related to progressive decreased spontaneous depolarization of pacemaker cells. The conduction system is also affected, with prolongation initially noted in the PR interval, then QRS complex, then QT intervals.²¹ Atropine is ineffective. The myocardium becomes irritable. As temperature falls lower than 32° C, atrial fibrillation is common, usually preceding ventricular fibrillation that may occur spontaneously when temperature falls below 28° C (82° F). Asystole usually occurs at temperatures less than 25° C.²²

Respiratory Changes

Early in hypothermia (34-36° C) the respiratory drive is stimulated. The minute ventilation increases in response to increased oxygen consumption and CO₂ production. Below 33° C, respiratory depression takes place. Minute ventilation decreases. Depressed cough reflex and ciliary action coupled with increased production of mucus (bronchorrhea) increase the risk of atelectasis and aspiration. Noncardiogenic pulmonary edema has also been reported.^{23,24}

Renal Changes

The initial response to hypothermia includes increased renal blood flow secondary to an increase in blood pressure and cardiac output, inducing diuresis. As hypothermia progresses below 32° C and cardiac output declines, renal blood flow and glomerular filtration rate decrease. This response sets the stage for acute renal failure but without affecting urinary output secondary to impaired renal tubular sodium reabsorption, a condition that maintains ongoing diuresis (cold diuresis). This response explains why hypothermia patients may present with profound intravascular volume depletion.^{6,16,25}

Gastrointestinal Changes

Ileus, bowel wall edema, depressed hepatic detoxification, punctate gastric erosions, and rarely hemorrhagic pancreatitis are among the gastrointestinal manifestations of hypothermia.¹⁶

LABORATORY EVALUATION

Laboratory evaluations should be obtained to assess metabolic status and organ dysfunction. The following are common laboratory findings during hypothermia. They usually change with rewarming and require frequent monitoring.

ARTERIAL BLOOD GASES

As temperature decreases, the oxyhemoglobin dissociation curve shifts to the left. For every 1° C drop in temperature, pH increases by 0.015, PaO₂ decreases by 7.2%, and PaCO₂ decreases by 4.4%. Because all arterial blood gas (ABG) samples are warmed to 37° C (98.6° F) when measured, the pH appears lower and the PaO₂ and PaCO₂ appear higher than the patient's actual values. Most knowledge on acid-base status during hypothermia comes from cardiovascular surgery reports. Although most literature does not recommend correction of temperature to guide therapy, the use of corrected values should be strictly individualized.²⁶⁻²⁸

COMPLETE BLOOD COUNT

Hemoconcentration, an increase in hematocrit secondary to a decrease in plasma volume, is common (2% for each 1° C decrease in temperature). An initial low hemoglobin suggests acute hemorrhage or preexisting anemia. White blood cells (WBCs) may decrease; therefore, any history suggestive of infection should prompt treatment with antibiotics in high-risk groups such as the elderly, neonates, and the immunocompromised.²⁹

COAGULATION FACTORS

Hypothermia induces inhibition of coagulation factors. It also induces thrombocytopenia secondary to bone marrow suppression and splenic and hepatic sequestration, as well as reduction in platelet adhesions and aggregation. Prolonged bleeding time and clotting times are common. Coagulation tests in the laboratory are performed under 37° C. If normal, they may not negate the presence of underlying hypothermia-induced coagulopathy. The key treatment in this condition is rewarming, not supplementation of coagulation factors.^{30,31} Rewarming, however, increases the clotting response. Clinicians should use caution during this process, as patients are more susceptible to negative cardiovascular events.⁴

BLOOD UREA NITROGEN/CREATININE/ELECTROLYTES

As mentioned earlier, acute renal failure with intravascular volume depletion and decreased renal perfusion is encountered. This is usually associated with higher levels of blood urea nitrogen (BUN) and creatinine (Cr) secondary to decreased clearance. Recurrent evaluation of electrolytes is essential during rewarming because no consistent pattern is present. Either hypo- or hyperkalemia may complicate the course of hypothermia and should be corrected promptly. Hypothermia masks the usual electrocardiogram (ECG) changes seen in normal hyperkalemia.^{6,8,16}

BLOOD GLUCOSE

Hyperglycemia is initially noted as hypothermia inhibits insulin release and insulin uptake by membrane receptors at temperatures less than 30° C. It is further exacerbated by increased catecholamines. Insulin at these temperatures is ineffective. Exogenous insulin should be avoided, as it may cause rebound hypoglycemia during rewarming.³²

OTHER LABORATORY ABNORMALITIES

Hyperamylasemia is common and may be related to a preexisting pancreatitis or pancreatitis induced by

hypothermia. Hyperamylasemia correlates with the severity of hypothermia. Variable elevation in creatine phosphokinase levels may reflect underlying rhabdomyolysis.

ELECTROCARDIOGRAPHY CHANGES

All intervals—PR, QRS, and QT—are prolonged secondary to hypothermia-induced slowed impulse conduction through potassium channels. When body temperature decreases below 33° C (91.4° F), the J (Osborn) wave may be noted as a positive deflection in the left ventricular leads at the junction of the QRS complex and ST segment in 25% to 30% of patients. The presence of this wave is not pathognomonic and has no prognostic implication. The magnitude of the Osborn wave is associated with the degree of severity of hypothermia.^{12,21}

MANAGEMENT (SEE FIG. 69.2)

The severity of hypothermia, clinical findings, and comorbid conditions of the patient are important factors for determining the aggressiveness of resuscitation techniques. Once hypothermia is confirmed, assessment and treatment of the critically ill patient should take place simultaneously. Some patients with hypothermia and cardiac arrest achieved an almost complete recovery despite prolonged resuscitation with a temperature as low as 13.7° C. Patients with moderate or severe hypothermia should be resuscitated until adequate rewarming is achieved before declaring efforts as unsuccessful.³³⁻³⁵

INITIAL STABILIZATION

Removal of wet clothing and moving the patient to a warm environment for protection against continued heat loss are essential. Rough movements of the patient's body during physical assessment should be avoided as it could precipitate serious cardiac arrhythmias. Continuous monitoring of cardiac status and core temperature should be established without delay. Similar to any emergency situation, airway, breathing, and circulation should be evaluated promptly in the hypothermic patient.

AIRWAY/BREATHING SUPPORT

Chest rigidity and decreased diaphragmatic movement impede adequate ventilation. Oxygenation may be insufficient secondary to underlying aspiration or pulmonary edema. Supplemental oxygen should be provided to alert patients with intact airway reflexes pending full assessment of oxygenation status. Hypothermic patients with apnea, deteriorating mental status, or loss of protective reflexes should undergo endotracheal intubation. The oropharyngeal route is preferred. Jaw maneuvering could be difficult in this category of patients secondary to muscle rigidity. Neuromuscular blocking agents do not have a role as they are ineffective at temperatures below 30° C. Intubation with a smaller endotracheal tube may be attempted. Intubation is unlikely to induce dysrhythmias in hypothermic patients.⁸

CARDIOCIRCULATORY SUPPORT

Volume Resuscitation

Most patients with moderate to severe hypothermia suffer from volume depletion. Continuous warmed intravenous fluids (40-42° C) should be administered. Peripheral

large-gauge catheters are the preferred route of administration. The femoral vein is the preferred site if a central line is anticipated. Volume status should be monitored continuously during rewarming, as peripheral vasodilation and hypotension are likely to occur.³⁶

Cardiac Resuscitation

Patients with moderate to severe hypothermia should undergo a thorough evaluation, looking for signs of cardiac output or peripheral blood flow. Echocardiography and Doppler ultrasound can be utilized for this purpose. Cardiopulmonary resuscitation should be performed immediately if no pulse or a nonperfusing rhythm (ventricular fibrillation or asystole) is established.³⁷⁻³⁹

Defibrillation. The hypothermic heart may be unresponsive to cardioactive drugs, attempted electric pacing, and defibrillation. Most arrhythmias other than ventricular fibrillation tend to convert spontaneously with rewarming. Sinus bradycardia does not require pacing or pharmacologic intervention. Ventricular fibrillation or tachycardia without a pulse requires initial defibrillation with maximum energy. If unsuccessful, rewarming is initiated. Defibrillation is reattempted after every 1° to 2° C increase in core temperature or when temperature rises above 30° to 32° C.³⁷⁻³⁹

Cardioactive Drugs. The antiarrhythmic and vasoactive drug efficacy in moderate to severe hypothermia is not well determined. It is mainly based on animal studies. Epinephrine and vasopressin may increase coronary perfusion but not survival. According to the American Heart Association 2010 guidelines, it may be reasonable to consider administration of a vasopressor during cardiac arrest according to the standard ACLS (advanced cardiac life support) algorithm concurrent with rewarming strategies. Isolated use of antiarrhythmics does not appear to be beneficial. In general, these drugs are withheld until rewarming achieves a temperature above 30° C, and then the lowest effective dose should be administered. Caution should be exercised not to administer these drugs repeatedly, as toxic accumulation can occur secondary to decreased metabolism. As normothermia is approached (above 35° C), standard drug protocols are used.³⁷⁻³⁹

ADDITIONAL SUPPORT

A nasogastric or orogastric tube should be placed in patients with moderate to severe hypothermia to relieve gastric distention. This tube also might help reduce vomiting and aspiration secondary to gastric dysmotility. A urinary catheter is also essential to monitor urine output and assess volume resuscitation efforts. Intra-arterial catheters for pressure monitoring should be used selectively. A Doppler ultrasound device may be necessary. Pulse oximetry is unlikely to be accurate given the poor perfusion to the extremities.

REWARMING METHODS

There are several methods of rewarming. Selection depends on the severity of hypothermia and the clinical condition of the patient. Controlled clinical studies and interventional studies are limited, and evidence-based protocols are lacking. Absence of a developed protocol led to the use of a wide variety of treatment strategies, depending on the

expertise and previous exposure of the clinical teams and hospital resources.⁴⁰

Passive External Rewarming

Passive external rewarming is the method of choice for hemodynamically stable patients with mild hypothermia (above 32° C), adequate physiologic reserve, and intact mechanism of shivering. Treatment includes placement of patients in a warm environment, removal of wet clothing, and application of insulating materials, such as blankets, to prevent heat loss. This method is expected to raise core temperature by 0.5° to 2.0° C per hour.⁶ If unsuccessful, active rewarming is initiated.

Active Rewarming

Active External Rewarming. Active external rewarming (AER) is applied to patients with a core temperature between 86° and 92° F (30-34° C) without potential compromise of airway or hemodynamic status. It involves one or a combination of techniques, including warming blankets, heating pads, radiant energy, and forced heated air systems. Few complications (such as thermal injuries in the form of skin burns) have been reported using these methods. “After drop” is a phenomenon that was reported as a complication of AER. When the extremities and the trunk are warmed simultaneously, cold acidemic blood returns to the central circulation from the periphery secondary to vasodilation, causing a paradoxical decrease in core temperature. This drop worsens acidemia, precipitating hypotension and arrhythmias that can be fatal. Therefore, it is advised to apply rewarming strategies to the trunk before the extremities.^{41,42}

Estimated rates of rewarming using this method ranges from 0.8° C with heating blankets up to 2.5° C per hour with the forced air rewarming systems. This forced air system is the most widely used by clinicians because it is easy and effective.^{41,42}

Active Internal Rewarming. Active internal rewarming (AIR) is used for patients with moderate to severe hypothermia (under 86° F or 30° C) with adequate hemodynamics, in conjunction with AER.⁴³ Methods include administration of warmed intravenous fluids (40-42° C) and warmed humidified air (40-45° C) through a mask or endotracheal tube. Intravenous fluids alone are not adequate but prevent further heat loss. It is estimated that an average 1 L crystalloid (40-42° C) for a 70-kg person will increase the temperature by 0.3°. Rewarming by heated oxygen by endotracheal tube is more effective than a facemask. A total rate of 1° to 2.5° C per hour is anticipated by this method.^{15,43,44} Gastric bladder and colonic irrigation are of limited value secondary to their small surface area.

Peritoneal and Pleural Lavage

If rewarming is inadequate, more aggressive methods include peritoneal and pleural lavage. In pleural irrigation, two large-bore (36F or greater) thoracotomy tubes are used. One tube is placed at the midclavicular line and is connected to saline at 42° C (107.2° F). The other tube is placed at the posterior axillary line and is connected to a chest tube drainage.⁴⁵

Peritoneal lavage and dialysis are achieved by placement of a peritoneal catheter (8F) into the peritoneum and

infusing 10 to 20 mL/kg of warmed 42°C isotonic fluid. The fluid is kept in the peritoneal cavity before it is removed.¹⁵

Extracorporeal Methods of Rewarming

This approach is the most effective method in raising core body temperature.

Hemodialysis. Hemodialysis is appropriate for patients with severe hypothermia and accompanying hyperkalemia and renal failure. The benefit is that hemodialysis is widely available and practical. It is portable and efficient. The rewarming rate ranges between 2° and 4° C per hour, but it requires the absence of circulatory collapse.⁴⁶

Continuous Arteriovenous Rewarming. Continuous arteriovenous rewarming (CAVR) has the ability to maintain circulation, correct hypoxia, and replenish intravascular volume without the need for systemic anticoagulation. The rate of rewarming ranges between 3° and 4° C per hour and requires a systolic blood pressure of at least 60 mm Hg to be performed.

Continuous Venovenous Hemofiltration. Continuous venovenous hemofiltration (CVVH) has also been reported to achieve successful rewarming. It is widely available, can be performed with lower blood pressure, but provides slow rewarming rates (1-3° C per hour). It does not provide full circulatory support, and volume resuscitation is necessary when cardiac output is inadequate. Chest compressions and ventilation must be continued until the return of spontaneous circulation. However, it may prove to be an alternative to CAVR when limited by profound hypotension.

Cardiopulmonary Bypass. Cardiopulmonary bypass (CPB) is the standard of care for patients with severe hypothermia, apnea, and cardiac arrest or hemodynamic instability. It provides rapid rewarming rates (8-12° C per hour) while maintaining oxygenation, circulation, and rapid correction of metabolic derangements. However, the need for CPB in hypothermic trauma patients may be limited secondary to the need for systemic anticoagulation. In addition, the expert teams required for CPB make the implementation somewhat challenging.^{6,15,38} Portable CPB systems are available.

Extracorporeal Membrane Oxygenation. There is a growing body of evidence that extracorporeal membrane oxygenation (ECMO) could be more preferable to CPB. It has the same rate of rewarming (8-12° C per hour).³⁸ In patients undergoing rewarming, ECMO may reduce the risk of multiorgan failure secondary to reperfusion. It can be continued for several days and needs less anticoagulation.

Endovascular Temperature Control Device. Endovascular temperature control device has been reported in recent years as another tool for rewarming in patients with severe hypothermia. It is generally placed in the emergency department in cool comatose survivors of cardiac arrest. It can also be used to warm patients with accidental hypothermia. Because the same device is used in both sets of patients, the operation of the equipment is familiar to both the

emergency department and ICU staff. The only procedure required to place this device is a central venous catheter, which is less invasive than CPB or pleural lavage.

PROGNOSIS

Different reports on the outcome of moderate to severe hypothermic patients have been variable. Multiple confounding factors exist that make it difficult to predict survival. Older age, lower core body temperature, indoor exposure, submersion, trauma, toxin ingestion, prehospital hemodynamic status, BUN and potassium levels, the need for intubation, and presence or absence of asphyxiation are significant predictors of outcome. For patients undergoing CPB for hypothermia and hemodynamic instability, favorable factors for survival are associated with younger age, higher arterial pH, lower PaCO₂, lower serum potassium levels, and the absence of asphyxia and suffocation.¹⁸ Many patients die even after achieving adequate rewarming secondary to multiorgan failure. Knowing its detrimental outcome, an important approach should pursue prevention. In general, hypothermia is a preventable condition. Public health education and preparedness should be directed toward populations at risk.

HYPERTHERMIA

HISTORY AND INCIDENCE

Innumerable military campaigns throughout history were lost as a result of heat illness, long before the enemy ever raised a weapon. In modern times, the Israeli Six-Day War during the late 1960s provides the best example of the ravages of heat illness. The Israeli army had forced water consumption policies, by the clock, including strict disciplinary measures for evidence of heat injury due to negligence. By contrast, the Egyptian army did not have well-enforced policies. In the end, the Israeli army's heat injury statistics were negligible, but more than 50% of the Egyptian soldiers in the same locale suffered from heat illnesses that rendered them unable to effectively perform their expected tasks.

Heatstroke and hyperthermia have been identified as the environmental diseases least frequently monitored by epidemiology systems in the United States. Serious heat illness has received considerable recent attention owing to catastrophic heat waves in the United States and Europe, the deaths of high-profile athletes, and military deployments. The exact incidence of heatstroke in the United States is unknown. The CDC reported that between the years 1987 and 1988, 1092 death certificates listed excessive heat as either a primary or a secondary cause.⁴⁷ It is suspected that a number of other heat-related severe illnesses and deaths occur each year that are attributed to other causes. Guidelines from the National Association of Medical Examiners suggest that in cases in which the measured antemortem body temperature at the time of collapse was 105° F (40.6° C) or higher, the cause of death should be certified as heatstroke or hyperthermia. Deaths also may be certified as heatstroke or hyperthermia with lower body temperatures when cooling has been attempted before arrival at the

hospital or when the clinical history includes mental status changes and elevated liver and muscle enzymes.⁴⁸

PATHOGENESIS

Heatstroke is a complex syndrome of end-organ dysfunction initiated by hyperthermia that occurs when heat accumulation in the body overwhelms heat-dissipating mechanisms. The diagnosis of heatstroke should be considered in patients with core body temperatures greater than 41°C, or in patients with a core temperature of 40.6°C and concomitant mental status changes. Because anhidrosis is a late finding and sweating may be observed in severely hyperthermic patients, diaphoresis should not be considered a discriminatory finding. Heatstroke traditionally is subdivided into exertional and nonexertional causes. **Box 69.1** outlines examples of diseases and conditions within each of these categories. To understand the pathogenesis of heatstroke, the systemic and cellular responses to heat stress must be appreciated. These responses include thermoregulation (with acclimatization), an acute-phase response, and a response that involves the production of heat shock proteins.

THERMOREGULATION

At basal metabolic levels, less than 100 kcal of metabolic heat is generated per hour. However, when physical activity increases, heat production may rise as high as 900 kcal/hour. This level of heat production is capable of raising the core body temperature by 1°C every 5 to 8 minutes. Heat is dissipated via evaporation, conduction or radiation, and convectional losses. Cutaneous vasodilation results in heat loss through all of these physical mechanisms except evaporation. Unfortunately, when the ambient temperature exceeds body temperature, only evaporative losses associated with perspiration actually dissipate heat. Perspiration can produce a maximum rate of heat loss of approximately 400 to 650 kcal/hour in acclimatized persons. When heat production exceeds this threshold, body temperature quickly begins to rise.

Box 69.1 Conditions and Diseases Associated with Heatstroke

Exertional Causes

Environmental: high ambient temperatures/humidity
Physiologic: lack of physical conditioning, inadequate acclimatization, or overexertion

Nonexertional Causes

Environmental: high ambient temperatures/humidity, lack of air conditioning, lack of shrubbery/trees around dwelling, height of home above ground level
Physiologic: age older than 65 years, alcoholism, congestive heart failure, renal failure, diabetes mellitus, chronic obstructive pulmonary disease, dementia, schizophrenia, cystic fibrosis, thyrotoxicosis, hypokalemia, dehydration
Drugs: alcohol, antidopaminergics, anticholinergics, amphetamines, beta blockers, butyrophenones, cocaine, diuretics, hallucinogens, tricyclic antidepressants

ACCLIMATIZATION

Acclimatization is a physiologic term that collectively describes various adaptive responses to repeated heat stress. Many of these responses are directed at conserving plasma volume. They include decreased total sweat sodium concentration and nonreflexively increased aldosterone secretion. In addition, acclimatized people tend to drink greater volumes of water and have measurable increases in extracellular fluid volume beyond that of nonacclimatized persons. Ultimately, maximum cardiac output and stroke volume increase, while maximum heart rate and O₂ consumption decrease (improved efficiency per unit of metabolic work expended).⁴⁹ Similarly, the net amount of heat generated per unit of work expended also decreases.

ACUTE-PHASE RESPONSE

The acute-phase response, involving endothelial cells, leukocytes, and epithelial cells, protects body tissues from heat-induced tissue injury. A variety of immunomodulatory and inflammatory cytokines are released in response to increased endogenous or environmental heat, including interleukin 6 (IL-6), tumor necrosis factor- α (TNF- α), IL-10, IL-12, and interferon.

HEAT SHOCK RESPONSE

Cells respond to heat by production of inducible heat shock proteins that help induce a state of tolerance to heat stress. These proteins function as molecular chaperones that bind to partially folded or misfolded proteins and thereby prevent their irreversible denaturation. Heat shock proteins also may help regulate the baroreceptor reflex response during heat stress, abating hypotension and bradycardia.

PREDISPOSING FACTORS

The epidemiology of heatstroke parallels that of hypothermia—nonexertional heatstroke is seen in elderly, alcoholic, or otherwise debilitated patients in urban areas. By contrast, exertional heatstroke develops in otherwise healthy people who overexert themselves in exceedingly hot or humid conditions. Like hypothermia, heatstroke most often develops in patients with impaired thermoregulation. Antidopaminergic drugs, alcohol, and primary central nervous system (CNS) disorders are common denominators in many patients.⁴⁹ A number of environmental and socioeconomic conditions have been associated in recent years with heatstroke.^{50,51} A lack of air conditioning and a lack of trees or shrubbery around homes are commonly observed in patients presenting with heatstroke. People who are apartment bound, particularly those on higher floors, also appear to be at higher risk during summer heat waves. Finally, elderly patients not only have diminished temperature perception but also do not produce the same volume of sweat, placing them at higher risk for the development of heatstroke.

Many drugs, “recreational” and prescription, are associated with an increased risk of hyperthermia and deserve further emphasis. Cocaine causes generalized sympathetic activation and loss of response to environmental cues. It is rapidly becoming a leading cause of heatstroke in many urban emergency departments. Beta blockers, on the other

hand, have been implicated in heatstroke through a drug-mediated direct decrease in sweat gland production. Diuretics decrease baseline circulating plasma volume, leading to decreased sweat production. Hypokalemia decreases sweat gland output as well, and barbiturates can even cause sweat gland necrosis. When a heat wave arrives in an urban area, any one or several of the foregoing factors combined can lead to outbreaks of heat injury.

PRESENTATION AND CLINICAL MANIFESTATIONS

Nonexertional heatstroke may manifest insidiously.⁵² An urban setting and the recognized presence of a heat wave may be the best available diagnostic clues. Some form of CNS dysfunction is nearly universal in patients with nonexertional heatstroke. The spectrum of dysfunction ranges from increased irritability and confusion to stupor and coma. Hyperpyrexia often is the most specific physical finding. In many cases, the presentation of an elderly patient with an altered mental status, irritability, and a high fever suggests sepsis. However, epidemiologic associations, concurrent debilitating disease, and the impact of medications that limit thermoregulation should be considered before limiting therapy to empiric antibiotics and antipyretic medications.

Exertional heatstroke typically occurs more suddenly and with a more self-evident clinical history.⁵³ Severe dehydration, anhidrosis, and extreme hyperpyrexia are common in external heatstroke. Affected persons appear hyperdynamic, with tachycardia, increased cardiac output, and peripheral arterial vasodilation. CNS dysfunction is somewhat less common in this patient subset. Initially, thermoregulation is intact in patients with exertional hyperthermia. At high core body temperatures, however, metabolic activity overwhelms normal heat dissipation mechanisms, and clear-cut disruption of normal thermoregulation may then appear. Hyperthermia is further accelerated by the loss of effective sweating for evaporative heat dissipation. Myocardial dysfunction with depression of left ventricular ejection fraction also has been described after heatstroke, which resolves with treatment.⁵⁴

In addition to alterations of consciousness, hallucinations, focal neurologic deficits, various cranial nerve abnormalities, and opisthotonos are well described. Seizures occur in greater than half of these patients and may be related strictly to core body temperature or to concomitant disorders of free water-electrolyte balance. Decerebrate posturing also is rarely observed in some patients without other known mechanisms of acute brain injury. Many patients may suffer residual defects such as dementia, personality changes, focal deficits, cerebellar changes, or pyramidal findings. Nevertheless, many patients also proceed to complete recovery, suggesting that early findings should not deter acute management.⁵¹

DIAGNOSTIC APPROACH

In addition to CNS dysfunction, rhabdomyolysis is a frequent feature of exertional hyperthermia. Manifestations sometimes include tender, edematous muscles and “cola-colored” urine, but the condition more commonly is defined by elevation in total creatine kinase (CK), serum aldolase,

uric acid, or serum potassium (alone or in combination). Hyperkalemia in this situation may be life-threatening.

Acute renal failure occurs in up to one third of patients with heatstroke.⁵⁵ It is considerably more common in patients in whom rhabdomyolysis is a feature (i.e., with myoglobinuria or urate nephropathy). However, direct heat injury and renal hypoperfusion also may contribute. Acute tubular necrosis in heatstroke typically manifests with oliguria, non-nephrotic range proteinuria, and abundant granular cast formation.

Evidence of hepatocellular injury is present to some degree in essentially all patients with heatstroke and is attributed principally to a direct toxic effect of hyperthermia on hepatocytes.⁵⁶ Elevation of serum transaminases is a cardinal feature of this toxicity and often is observed within 30 minutes of syndrome onset. So prevalent is this finding that the absence of transaminitis should cast serious doubt on the diagnosis of heatstroke. Histologic changes including centrilobular necrosis have been observed within 24 hours of heat injury and evolve over the ensuing days. Transaminase and lactate dehydrogenase levels typically peak on the third or fourth hospital day, and depending upon the extent of injury, these changes may be accompanied by increased alkaline phosphatase levels, hyperbilirubinemia, and a prolonged prothrombin time. Overall, fulminant hepatic necrosis is rare; however, hepatic insufficiency contributes to late morbidity and death in patients who survive the initial resuscitation.⁵⁷ Prolongation of coagulation times also may be due to disseminated intravascular coagulation (DIC). Although DIC also is rare, it is a marker of poor prognosis when present. Clinical manifestations of DIC range from isolated laboratory abnormalities to generalized bleeding. In patients with heatstroke, DIC may exacerbate hepatic injury and is associated with the development of acute respiratory distress syndrome (ARDS). In fact, the codevelopment of DIC and ARDS in patients with heatstroke is predictive of a high mortality rate (>75%). Qualitative coagulation function (including platelet function) also may be impaired by heat injury. The clinical effects of these impairments are variable.

A range of electrolyte abnormalities related to renal failure and dehydration in heatstroke victims has been well described and includes hyponatremia, hypocalcemia, hypokalemia (hyperkalemia in patients with acute tubular necrosis or rhabdomyolysis), hypophosphatemia, and hypomagnesemia. Of these, hyponatremia and free water excess may produce severe neurologic effects including central pontine myelinolysis (CPM). CPM has been reported in patients with heatstroke who receive aggressive prehospital resuscitation with hypotonic solutions. Serum osmolality should be carefully monitored during volume resuscitation, and intravenous solutions should be modified accordingly. Severe lactic acidosis is especially common in patients with exertional heat injury.⁵⁸ Finally, arterial blood gas results are influenced by temperature in a fashion opposite that described with hypothermia (Box 69.2).

APPROACH TO MANAGEMENT

Duration of extreme hyperpyrexia is the single most important determinant of morbidity and fatality in all patients with heatstroke (both exertional and nonexertional). Therefore, expeditious cooling should be initiated

Box 69.2 Temperature Correction Factors for Arterial Blood Gas (ABG) Specimens*

ABG Component Correction Factor

$$\begin{aligned} \text{pH} &+ 0.015 (37 - T_c) \\ \text{PaO}_2 &- 0.072 (37 - T_c) \times \text{PaO}_2 \\ \text{PaCO}_2 &- 0.044 (37 - T_c) \times \text{PaCO}_2 \end{aligned}$$

Example

A patient presents with a core temperature of 32°C with the following ABG values: pH = 7.12, PaCO₂ = 52 mm Hg, and PaO₂ = 52 mm Hg. Corrections for temperature are as follows:

$$\begin{aligned} \text{pH} &= 7.12 + [0.015 (37 - 32)] = 7.195 \\ \text{PaO}_2 &= 52 - [0.072 (37 - 32) \times 52] = 33.28 \text{ mm Hg} \\ \text{PaCO}_2 &= 52 - [0.044 (37 - 32) \times 52] = 40.56 \text{ mm Hg} \end{aligned}$$

These corrections also may be used for hyperthermia.

*ABG values not corrected for temperature in significantly hypothermic patients yield falsely low pH and falsely elevated PaCO₂ and PaO₂ values.

T_c, core temperature.

simultaneously with other basic and advanced life support modalities. Indeed, a review of outcome data for heatstroke victims during the Chicago heat wave of 1995 suggested that computed tomography imaging of the brain contributed little to patient management and simply delayed efforts to rapidly cool the patient.⁵⁹ General supportive measures and specific measures for cooling the patient are discussed next.

SUPPORTIVE MEASURES

Intravascular volume restoration must be individualized. In general, patients with exertional hypothermia are severely hypovolemic. Hemodynamic monitoring has demonstrated that patients may manifest two distinct responses to heatstroke: (1) a hyperdynamic response with an elevated cardiac index (CI) and depressed systemic vascular resistance (SVR) and (2) a hypodynamic response with depressed CI and elevated SVR.⁵⁵ Although the hypodynamic response may be more common in older patients with preexisting medical problems and classic heatstroke, severe hyperthermia can lead to myocardial dysfunction even in young, healthy adults without preexisting cardiac disease. Overzealous volume resuscitation in this setting can produce significant pulmonary congestion. The rapid restoration of an adequate perfusion pressure without pressor support is a reasonable goal, and if this is achieved, further volume resuscitation should proceed at a more measured pace. Pulmonary artery catheterization is recommended early in the clinical course for patients with unclear cardiovascular physiology. Finally, isoproterenol traditionally has been considered the inotrope of choice for patients with severely depressed myocardial performance. Its lack of α -activity ensures that heat dissipation is not impeded. Dobutamine may be a more rational choice, however, because it has considerably fewer myocardial irritant and arrhythmogenic properties.

Seizures are treated according to standard guidelines. Benzodiazepines are used for acute, ongoing convulsive

activity. Dilantin is useful for added control or prophylaxis; however, hypotension with rapid intravenous infusion should be anticipated. Barbiturates also are effective antiseizure drugs but should be reserved as second-line therapeutic agents because of their theoretical impediment to sweat formation and heat dissipation.

Acute renal failure should be approached aggressively in patients with rhabdomyolysis. Intravascular volume repletion should be promptly accomplished, with continued infusion of volume to produce forced diuresis. Mannitol or loop diuretics may be of value to maintain appropriate urine output. Hyperkalemia management may be challenging. The clinician should not hesitate to administer glucose, insulin, and calcium in patients with ECG changes. Subsequent sodium polystyrene sulfonate (Kayexalate) dosing may also be required.

COOLING MEASURES

Effective heat dissipation depends on the rapid transfer of heat from the core to the skin and from the skin to the external environment. In persons with hyperthermia, transfer of heat from the core to the skin is facilitated by active cutaneous vasodilation. Therapeutic cooling techniques are therefore aimed at accelerating the transfer of heat from the skin to the environment without compromising the flow of blood to the skin, which can be accomplished by increasing the temperature gradient between the skin and the environment (for cooling by conduction) or by increasing the gradient of water vapor pressure between the skin and the environment (for cooling by evaporation), as well as by increasing the velocity of air adjacent to the skin (for cooling by convection).

Core body temperature should be rapidly cooled to a goal of 38° to 39°C. The most effective approaches to lowering the core temperature are immersion and evaporative methods. Of these, efficacy data related to ice-water immersion modalities historically have been better defined, with observed cooling rates of up to 0.13°C per minute. Similar efficacy has been noted with cool-water immersion as well, which should be less uncomfortable for both patient and staff members. Unfortunately, water immersion is not practical for many critically ill patients. Monitoring and treatment for arrhythmias, seizures, and other sequelae are problematic while the patient is immersed in a tub.

Evaporative techniques are quite effective and allow the ICU patient to be placed on a bed or other supportive surface and treated accordingly. The patient is repeatedly wetted with tepid water (not alcohol) or sprayed with water mist while warm air from a fan is blown across the body surface. Evaporative cooling by this method has shown a faster cooling rate in a canine model that is as effective as aggressive peritoneal lavage cooling, reaching rates as high as 0.32°C per minute.⁶⁰ An aggressive approach to cooling the heatstroke victim, whatever the approach, is most important. Other adjuncts to cooling include rectal, intraperitoneal, and gastric lavage with iced saline. These techniques are effective at rapidly lowering core temperature but are cumbersome and generally unnecessary and may lead to unwanted iatrogenesis.

Efforts to cool a patient should be discontinued when the core temperature falls to 38° to 39°C. At that point, a continued fall by 1° or 2°C is expected. Dantrolene sodium has

been used in some patients but was found to be ineffective in a double-blinded randomized study.^{61,62} Chlorpromazine may be useful in patients in whom shivering develops during active cooling efforts; however, if neuroleptic malignant syndrome (NMS) is in the differential diagnosis (and it often is), meperidine may be a better option than an antidopaminergic agent in patients with normal renal function.

SPECIFIC HYPERTHERMIC SYNDROMES

Malignant hyperthermia (MH) and NMS deserve special emphasis because of their potentially catastrophic impact on critically ill patients, particularly when they are not promptly recognized. MH is associated with use of certain anesthetic agents and can lead to profound skeletal muscle contraction and the subsequent development of life-threatening hyperthermia and other complications. NMS is caused by a variety of antipsychotic drugs and also leads to sustained muscular contraction and hyperthermia.

MALIGNANT HYPERTHERMIA

MH develops in approximately 1 of 15,000 patients who undergo surgical procedures requiring general anesthesia. The vast majority of cases are associated with either halothane or succinylcholine use; however, a variety of other drugs also have been implicated. Box 69.3 outlines these agents by type. Unlike in heatstroke, endogenous heat production is solely responsible for the observed hyperpyrexia. MH constitutes a true medical emergency because of the

Box 69.3 Anesthetics Associated with the Development of Malignant Hyperthermia and Neuroleptic Malignant Syndrome

Malignant Hyperthermia

Volatile Anesthetics

Dibenzoxepine

Loxapine

Dopamine-Depleting Drugs

Alpha-methyltyrosine, tetrabenzamine

Dopaminergic Agent Withdrawal

Levodopa-carbidopa, amantadine

rapid tempo at which severe sequelae evolve. Better recognition of this syndrome and modern treatment techniques, however, have reduced mortality rates from 70% to approximately 10% in recent years.

PATHOGENESIS

MH results from a rapid, sustained increase in myoplasmic Ca^{2+} levels in response to halogenated anesthetics and depolarizing neuromuscular blocking agents. Susceptibility to MH results from mutations in calcium channel proteins that mediate excitation-contraction coupling, with the ryanodine receptor calcium release channel (RyR1) representing the major locus. The mode of inheritance appears to be autosomal dominant, with variable penetrance. The phenomenon occurs in persons who have a mutation in the ryanodine type 1 receptor, resulting in a defective protein in the skeletal muscle sarcoplasmic reticulum membrane.⁶³ The uncontrolled rise in the myoplasmic Ca^{2+} concentration disables the troponin inhibition of actin and myosin, resulting in uncontrolled muscle tetany. This surge in muscle metabolic activity causes thermogenesis to increase exponentially and is rapidly followed by total body rigidity and extreme hyperpyrexia.

Numerous familial myopathies (such as Evans myopathy, King-Denborough syndrome, and central core disease) have been associated with the reaction.^{64,65} Curiously, this genetic predisposition does not translate into the predictable development of MH. That is, an initial challenge with an anesthetic drug that leads to MH does not consistently predict whether or not MH will occur with future exposures to the same drug. Measured contraction in caffeine or halothane preparations of muscle biopsy specimens is the most reliable predictor of risk for MH.

PRESENTATION

MH is characterized by the triad of (1) severe hyperthermia, (2) muscle rigidity, and (3) metabolic acidosis. MH usually is an acute and rapidly progressive process; however, many reports suggest that the syndrome may vary considerably in severity and rate of progression. In the anesthesia setting, capnography may provide the earliest clue of impending MH, as end-tidal CO_2 rises in response to the increased metabolic rate. Clinical harbingers of impending MH include masseter muscle rigidity or trismus and tachycardia, which is reported to occur in greater than 95% of patients.⁶⁴ Cyanosis, increased blood pressure, and increased respiratory rate all may be observed with the onset of the reaction as the hypermetabolic response is triggered.

Muscle rigidity may explosively progress from localized masseter contraction to diffuse rigidity of skeletal muscle groups. When uninterrupted, this process will lead to progressive, severe hyperthermia. Extreme hyperpyrexia is considered a late finding in MH. Mortality risk has been related to peak core body temperature, reflecting both MH severity and delayed recognition. With progressing rigidity, a mixed metabolic and respiratory acidosis may occur, along with a variety of other electrolyte abnormalities, including hyperkalemia, hypercalcemia, and hypermagnesemia. Severe chest wall rigidity may even prevent adequate mechanical ventilation, leading to life-threatening hypoxemia and

hypoventilation. Rhabdomyolysis is reflected in elevated CK levels, usually greater than 1500 U/L and often greater than 10,000 U/L. Myoglobinuria may produce acute tubular necrosis with oliguric renal failure and severe DIC. High fever may result in myocardial dysfunction, pulmonary edema, and cerebral edema.

DIAGNOSIS

Susceptibility to MH can be identified unequivocally only by an *in vitro* muscle test. Fascicles of muscle obtained from the thigh by biopsy are exposed to halothane and separately to increasing concentrations of caffeine *in vitro*. The muscle contractures are increased in persons who are susceptible to MH. This test is now widely used to identify susceptibility to MH in patients who have had a reaction to inhaled halogenated anesthetics or suxamethonium that is suggestive of MH. If the test results in the propositus are positive, testing can be offered to first-degree relatives for genetic counseling. Patients whose biopsied muscle demonstrates a contracture to 3% halothane of 0.5 g or more and a contracture to 2 mmol/L caffeine of 0.2 g or more are considered to be susceptible to MH.⁶⁶ An *in vitro* contracture test is the gold standard for diagnosing susceptibility to MH. Two different protocols are used. European laboratories use the protocol devised by Ellis in Leeds with incremental doses of halothane up to 2% and incremental doses of caffeine. In the United States, a single dose of 3% halothane and incremental doses of caffeine are used. The two protocols give essentially the same results.⁶⁷

TREATMENT

By far, the most important measure for MH is the immediate cessation of any suspected triggering agents. If anesthesia must be maintained, nontriggering agents should be used. Agents considered safe in MH include barbiturates, narcotics, benzodiazepines, and propofol, to name only a few. Nondepolarizing neuromuscular blockers such as vecuronium or atracurium, although also considered safe in these patients, will do nothing to abort the MH reaction because the primary disease resides within the skeletal muscle cell itself—beyond the neuromuscular junction.

In addition to discontinuing offending agents, sodium dantrolene should be administered. Sodium dantrolene initially was tested as an antimicrobial; however, dantrolene was found to produce muscle weakness by blocking the Ca^{2+} efflux from the sarcoplasmic reticulum. The agent is capable of reversing the MH reaction by lowering myoplasmic Ca^{2+} concentrations. The onset of action usually is within 2 to 3 minutes, with initial responses including muscle relaxation, decreasing heart rate, and decreasing core body temperature. Muscle weakness may follow drug administration, but this should never limit proper therapy. After the initial response, dantrolene may be dosed orally for 24 to 48 hours. Late recurrences of MH have been reported if inadequate dantrolene dosing occurs. Intravenous preparations of dantrolene contain significant amounts of mannitol, which may produce a subsequent osmotic diuresis. Although this reaction may be desirable in patients with rhabdomyolysis, volume and electrolyte management should take this effect into account.

Systemic cooling may be best achieved in these complex patients with evaporative techniques, cooling blankets, cold saline infusion, or ice packs. Because of its similar actions on myoplasmic Ca^{2+} concentration, procainamide was the drug of choice for this syndrome before the advent of dantrolene therapy. Cardiac dysrhythmias not responding to electrolyte correction may be safely treated with procainamide or lidocaine. Numerous reports suggest that intravenous calcium may be safely infused for toxic hyperkalemia. Diltiazem and verapamil may interact with dantrolene to produce hyperkalemia; therefore, these agents should be avoided. Although the effects of MH on cardiac muscle remain unclear, some authors advocate that cardiac glycosides also should be avoided because they increase intracellular Ca^{2+} concentration.

NEUROLEPTIC MALIGNANT SYNDROME

NMS is an idiosyncratic reaction to neuroleptic drugs and other antidopaminergic agents. A number of drugs that are known to be associated with NMS are listed in [Box 69.3](#). NMS is characterized by muscle rigidity and altered mental status, followed by autonomic instability and hyperthermia. However, temperature elevations generally are less extreme than in MH and are not as life-threatening.

NMS is reported to occur in up to 2% to 3% of all patients receiving neuroleptic medications. The reaction typically develops within a few days of initiating therapy and almost always appears within the first 30 days. Curiously, NMS also occurs rarely in some patients after many years on a stable dosing regimen. Of importance, NMS also can occur in response to the withdrawal of central dopaminergic agonists such as bromocriptine or levodopa-carbidopa.

PATHOPHYSIOLOGY

Some investigators suspect that the genetic predisposition to MH also defines patients at risk for NMS, but most work has failed to demonstrate a relationship between NMS and altered sarcolemmal membrane calcium permeability. Unlike in MH, patients with NMS appear to have both increased heat production and impaired central thermoregulation, compromising heat dissipation. In these patients, a decrease in central dopaminergic tone also results in extrapyramidal signs of skeletal muscle rigidity and tremor and may account for alterations in mental status due to effects in the mesolimbic system and mesocortical pathways.⁶⁸ Finally, even though altered central thermoregulation may contribute to hyperthermia in NMS, rapid resolution of fever after administration of neuromuscular relaxing agents or dantrolene suggests that hyperthermia is due primarily to increased heat generation by skeletal muscle rigidity.

PRESENTATION

NMS should be considered when fever, muscular rigidity, catatonia, or dystonia occur in the setting of neuroleptic drug administration. Recent reviews have suggested the following criteria for the diagnosis of NMS: treatment with neuroleptics within 7 days; hyperthermia with core

temperatures greater than 38°C; muscle rigidity; exclusion of other systemic or drug-related illness; and any five of the following: altered mental status, tachycardia, hypertension or hypotension, tachypnea or hypoxia, diaphoresis or sialorrhea, tremor, incontinence, CK elevation or myoglobinuria, leukocytosis, or metabolic acidosis.^{68,69}

Altered mental status commonly precedes the onset of other symptoms and may manifest as confusion or agitation. More severe cases may progress to obtundation or coma, or may manifest as a mute catatonia that is difficult to differentiate from lethal catatonia. Muscle rigidity typically involves the neck, shoulders, and limbs but may compromise ventilation if chest wall involvement is severe. Other neuromuscular findings are diverse and may include dysarthria, dyskinesias, ataxia, or tremors.

Autonomic findings typically include diaphoresis, hypertension, and tachycardia. However, hypotension may develop in some patients. Fever is a late finding and usually occurs in the range of 38° to 42°C. When fever exceeds 42°C, it may cause end-organ damage like that seen in other hyperthermia syndromes.

Rhabdomyolysis occurs often, though it usually is of a milder caliber than that observed in MH or exertional heatstroke. Elevations in serum transaminases, BUN, and serum Cr often are seen, as well as a leukocytosis.

TREATMENT

When NMS is suspected, the offending drug should be discontinued immediately and supportive measures initiated. Volume resuscitation, physical measures for cooling, and monitoring of cardiopulmonary and renal parameters should be instituted immediately. Pharmacologic options for the treatment of NMS are more numerous than for other hyperthermia syndromes, because they may be directed toward restoring central dopaminergic tone or reducing peripheral rigidity until the neuroleptic effects subside.

Dopamine agonists such as bromocriptine, amantadine, and levodopa-carbidopa have been successfully employed in NMS.^{68,70} These agents act to directly increase central dopaminergic tone, thereby antagonizing the various effects of neuroleptic dopamine blockade. Regimens include bromocriptine or amantadine for up to 10 days before tapering. If a levodopa-carbidopa combination is used, it should be dosed four times a day owing to its shorter half-life. Some authors advocate avoiding central dopamine agonists if the diagnosis is unclear or if psychosis remains in the differential diagnosis, to avoid acutely exacerbating the psychotic state or contributing to a lethal catatonia.

Sodium dantrolene has been successfully used in numerous small series. The muscle relaxation that occurs helps to reduce temperature and decrease the sequelae of prolonged rigidity. Neuromuscular blockers also are effective at decreasing skeletal muscle tone, and in patients with high fever and autonomic instability, these agents offer a rapid means of establishing therapeutic effects. Combinations of central dopamine agonists and peripheral-acting agents have not as yet demonstrated a significant advantage over either treatment alone. Electroconvulsive therapy (ECT) has been used in a number of reports, but its advantages over supportive care alone have not been adequately

assessed.⁷⁰ Furthermore, the need for anesthesia presents an additional hazard that may complicate management in these patients.

Airway-protective reflexes should be vigilantly assessed because dystonia and impaired bulbar functions increase the risk of gastric aspiration in patients with NMS. Morbidity and mortality risks in these cases often arise from pulmonary complications such as aspiration, pneumonia, ARDS, or pulmonary embolism. Cardiac complications such as arrhythmias or myocardial infarction in more fulminant cases also contribute to fatality in these patients. As in all of the hyperthermia syndromes, worsening rhabdomyolysis and acute renal failure have been identified as signs of poor prognosis.

RHABDOMYOLYSIS

Rhabdomyolysis is a pathologic state in which the necrosis of muscle cells, through trauma, toxins, medications, or other causes, leads to an excess of intracellular solutes in the extracellular compartments. Target organ damage can range from minimal to severe depending on the degree of necrosis; the main consequences are metabolic abnormalities and acute kidney injury (AKI). Our understanding of the pathophysiology of rhabdomyolysis has evolved with an emphasis on early diagnosis and treatment, often in the setting of major catastrophes. The first report in the English literature, describing four cases of crush injury in Britain during World War II, was recently republished.⁷¹

EPIDEMIOLOGY

The incidence of rhabdomyolysis is dependent on the population undergoing analysis and the diagnostic criteria being used. It is recognized as a major cause of fatality following severe musculoskeletal injury from trauma.⁷² Following the 1999 Marmara earthquake in northwestern Turkey, 8.9% of hospitalized patients required renal replacement therapy for crush-related injuries.⁷³ Recently, a particular focus has been the ability of the HMG-CoA reductase (3-hydroxy-3-methyl-glutaryl-CoA reductase) inhibitor class of medications to cause rhabdomyolysis. Though likely a class phenomenon and rare overall, the incidence of rhabdomyolysis is not equivalent for all medications and is increased with the addition of other specific agents, in particular gemfibrozil, other fibrates, or cyclosporine.^{74,75} Additional causes of rhabdomyolysis are listed in [Box 69.4](#).⁷⁶⁻⁸¹ A recent review noted exogenous toxins, both prescribed and illicit, to be responsible for nearly 50% of cases.⁸²

Two additional scenarios that have received significant attention include “propofol infusion syndrome” and the potential for patients with sickle cell trait (SCT) to develop rhabdomyolysis. Both of these situations occur in younger patients. Propofol is rarely associated with a syndrome of metabolic acidosis and rhabdomyolysis. Risk factors include high-dose infusions over a prolonged period and a young age.⁸³⁻⁸⁶ SCT with subsequent rhabdomyolysis due to exertional sickling is now recognized as a cause for sudden deaths in young patients during strenuous workouts, in particular, football.⁸⁷⁻⁹³

Box 69.4 Causes of Rhabdomyolysis*

- Trauma/crush injuries
- Prolonged immobilization
- Electrical injury
- Excessive muscular activity
 - Excessive exertion especially in sickle cell trait patients
 - Malignant hyperthermia
 - Neuroleptic malignant syndrome
- Infections
 - Bacterial infections, in particular, those involving organisms causing pneumonia, muscle inflammation (pyomyositis), or sepsis
 - Viral infections including those due to human immunodeficiency virus, influenza virus, coxsackievirus, and Epstein-Barr virus
- Medications†
 - HMG-CoA reductase inhibitors
 - Gemfibrozil
 - Paraphenylenediamine (hair dye)
 - Phenothiazines
 - Theophylline
- Toxins
 - Cocaine
 - Carbon monoxide
 - Amphetamines including *N*-benzylpiperazine (BZP)-based medications
 - Alcohol
 - Tricholoma equestre* (wild mushrooms)
 - Hemlock
 - Animal venoms
- Metabolic myopathies¹²³
 - Carnitine palmitoyl transferase deficiency
 - Mitochondrial respiratory chain deficiencies
 - McArdle disease
 - Phosphofructokinase deficiency

*In addition to the causes listed here, risk factors include excessive heat, hyponatremia, hypophosphatemia, and hypokalemia.¹²⁴⁻¹²⁷

†Additional medications have been associated with rhabdomyolysis.^{76,128}

*Studies cited in this table may be found in the complete list of references for this chapter provided online.

HMG-CoA, 3-hydroxy-3-methyl-glutaryl-coenzyme A.

The epidemiology of rhabdomyolysis is limited by a lack of uniformity regarding the critical value in CK elevation needed to make the diagnosis. Threshold values above which rhabdomyolysis may occur vary and have ranged from 1000 to 10,000 U/L, though 5000 to 10,000 U/L are most common.⁹⁴ From an intensivist's perspective, CK elevations less than 5000 U/L should not be associated with myoglobin-induced renal failure unless clear additive causes such as volume depletion, sepsis, or radiocontrast are also present.

PATHOPHYSIOLOGY

The primary event in rhabdomyolysis is muscle cell necrosis resulting in the accumulation of sodium and calcium intracellularly; disruption of the cell membrane and excessive requirements for adenosine triphosphate accelerate this insult.^{95,96} As muscle cells undergo necrosis, intracellular substances are released and include potassium, uric acid,

phosphorus, lactic acid, and myoglobin. Under normal circumstances, haptoglobin binds any free myoglobin, thus prohibiting filtration across the glomerulus. As the haptoglobin binding is overwhelmed, free myoglobin is filtered and injures renal tubular cells. This process involves free radical toxicity. Additional causes include volume depletion, renal vasoconstriction, and tubular obstruction.^{76,97} Myoglobin and urinary tubular-protein casts are more prone to precipitation at a lower pH in experimental models. As a result, inducing an alkaline diuresis has been a traditional part of therapy for cases of rhabdomyolysis.⁹⁸

Research has suggested that it is the reperfusion of ischemic muscle as much as the ischemia itself that produces a high burden of oxygen-derived free radicals with subsequent cellular lipid membrane injury.⁹⁹ As renal function worsens, particularly when accompanied by intravascular volume depletion and renal failure, patients cannot excrete the high load of metabolites associated with muscle death, especially potassium.

Myoglobin release occurs across a spectrum of physical injuries from moderate exercise to lethal crush injuries. Myoglobinemia was noted in 39% of a cohort of Marine recruits, illustrating the frequency of mild muscle cell necrosis with strenuous exercise.¹⁰⁰ Obviously, not all such injuries lead to AKI. Beyond the actual amount of muscle necrosis, the development of AKI is most dependent on the degree of volume depletion present during the initial insult and the rapidity with which it is restored. Many of the syndromes that lead to the development of rhabdomyolysis, such as very strenuous exercise, crush injuries, or intoxications, are accompanied by volume depletion.

CLINICAL PRESENTATION

Patients with rhabdomyolysis present with a variety of symptoms. Often there is a history of injury, weakness, or muscle pain. Dark red or brown urine may or may not be present, depending on the amount of muscle necrosis and delay from injury. Frequently, the history is limited because of altered sensorium; clues include unexplained acidosis, hyperkalemia, hyperuricemia, hypocalcemia, elevations in CK not consistent with myocardial infarction, and unexplained renal failure. Recurrent presentations warrant an evaluation for a metabolic myopathy.¹⁰¹ Screening for rhabdomyolysis, through serial CK measurements, may be worthwhile in high-risk obese patients (body mass index over 56 kg/m²) undergoing gastric bypass surgery.¹⁰²

In most instances, serum CK will increase during the initial 48 hours of hospitalization. In a retrospective review of patients admitted to an ICU with rhabdomyolysis, defined as a CK greater than 10,000 U/L, significantly higher CK levels were associated with renal failure.¹⁰³ In the group with renal failure, the mean CK levels were 47,194 and 55,366 U/L at admission and peak, respectively; in the group without renal failure, the same levels were 17,531 and 28,643 U/L.

Although myoglobin is the most important protein in terms of nephrotoxicity, serum CK is routinely used in clinical practice as a marker of disease severity. This inconsistency is due to the widespread availability of the CK assay. Myoglobin clearance is not dependent on the kidneys and thus levels peak before CK levels.¹⁰⁴ Consequently, the CK levels being monitored for disease activity may not correlate

with the timing of the renal injury. AKI due to peak CK levels less than 5000 U/L should not be attributed to rhabdomyolysis unless the diagnosis was made substantially after the peak period of muscle cell necrosis; in this scenario, the CK levels will have decreased from a previously undocumented level.

The change of serum Cr in nonrhabdomyolysis oliguric AKI is usually not more than 1 mg/dL/24 hours. In rhabdomyolysis, Cr enters the intravascular compartment at a higher rate due to cell lysis, yielding an unusually rapid rise in serum Cr. In an early report, Grossman and associates noted a rise in Cr frequently greater than 2.5 mg/dL/day.¹⁰⁵ Speculation exists that this change in Cr may, in part, be due to the larger than average size in patients affected with rhabdomyolysis.¹⁰⁶ These same authors noted the impressive rate of renal recovery from rhabdomyolysis-induced AKI seen in the majority of patients; this high rate of recovery is now well recognized.

SPECIFIC TREATMENT REQUIREMENTS

The most important intervention to limit renal complications of crush-related injuries is early and aggressive volume resuscitation. Delays in initiation of intravenous fluid are associated with a higher frequency of patients requiring renal replacement therapy.¹⁰⁷ The damaged muscle cells provide a large reservoir for fluid sequestration; as a result large volumes of intravenous fluids have to be given and, ideally, should be instituted as early as possible, even on-site before victims of crush injuries are freed.^{78,108} A debate exists in the medical literature regarding the ideal type of volume resuscitation. As previously mentioned, alkaline diuresis has been shown in animal models to decrease the formation of myoglobin casts and subsequent AKI.⁹⁸ Similarly, mannitol is an agent favored for its proposed ability to scavenge free radicals and to reduce tissue swelling due to osmotically induced fluid removal from damaged muscle.^{109,110} These treatments have not been validated in well-designed, prospective trials. Retrospective studies suggest no benefit with the addition of mannitol or alkaline diuresis over normal saline alone.¹¹¹ In addition, there are potential risks to volume expansion with bicarbonate-based solutions or mannitol. They include the increased risk of calcium-phosphate complex formation and hypocalcemia from an increase in pH and the development of a hyperosmolar state when renal failure limits mannitol excretion. Finally, mannitol may *increase* the risk of renal failure in certain populations.¹¹² Risk factors for mannitol-induced AKI include kidney dysfunction, high-dose mannitol therapy, and use of cyclosporin A. In summary, volume expansion irrespective of the type of agent is the most important treatment modality. The focus on adequate diuresis is appropriate but presumes myoglobin-induced renal damage is ongoing. Intensivists often encounter patients whose myoglobin load is falling and whose renal insult has already occurred. Though the Cr may continue to rise, the onset of oliguria suggests limited benefit from further aggressive volume resuscitation, presuming adequate intravascular volume has been restored. In fact, given the good prognosis of AKI, overzealous volume resuscitation risks pulmonary compromise.

Historically, extremely aggressive volume resuscitation was pursued with an initial goal diuresis of up to 12 L/day,

presuming intact renal function. Less aggressive volume resuscitation may be equally protective though data are lacking. The focus on diuresis downplays the importance of establishing and maintaining adequate intravascular volume. Central venous pressure or other means to monitor intravascular pressure may be more useful to determine adequate resuscitation. It is also likely that the rapidity with which volume status is restored, irrespective of the type or quantity of diuresis, is the key determinant. Unfortunately, these guidelines are poorly studied in a prospective format.

In the setting of AKI requiring renal replacement therapy, the ideal modality is the one most easily accessible, assuming hemodynamic stability. Options include hemodialysis, peritoneal dialysis, and continuous modalities. Though continuous renal replacement modalities provide the best theoretical protection from ongoing metabolic and volume complications, its superiority has not been verified in rigorous trials. In cases associated with large-scale injuries such as earthquakes, the remaining infrastructure often dictates which dialytic modality can and should be provided.^{72,113} Historically, peritoneal dialysis has not been considered adequate in its ability to remove the large solute load present with rhabdomyolysis.¹¹⁴ Nonetheless, if it is the only available modality its potential role in managing rhabdomyolysis may be improved with more frequent exchanges. It should be noted that no traditional renal replacement method has the capability of removing myoglobin because of its size. However, considering the rapid extrarenal clearance of myoglobin it is unclear if therapy focused on myoglobin clearance will provide any superiority over current care. A novel approach recently evaluated the use of super high-flux (SHF) membranes to clear myoglobin during continuous venovenous hemofiltration.^{115,116} The authors demonstrated a fivefold increase in myoglobin removal but did acknowledge the potential for the removal of albumin, clotting factors, and protein-bound medications.

Hypocalcemia is common in rhabdomyolysis and may provide challenging management choices. Calcium entry into necrotic muscle cells often causes profound hypocalcemia. Calcium supplementation should be reserved for those patients with symptomatic hypocalcemia as hypercalcemia is a frequent finding during disease recovery.¹¹⁷ In addition, rapid increases in serum pH through the administration of intravenous bicarbonate may worsen hypocalcemia. Rasburicase has been reported to reduce hyperuricemia in young patients with rhabdomyolysis.¹¹⁸

Additional issues include close monitoring for limb ischemia due to compartment syndromes induced by muscle damage and subsequent fluid sequestration. Intracompartmental pressure monitoring may predict the need for intervention though research has suggested additional factors, most importantly hypotension and the difference between mean arterial pressure and intracompartmental pressures, influence whether compartment syndrome develops.¹¹⁹ The history, logic, and disappointing results of early and aggressive fasciotomy have recently been described.¹²⁰ Mannitol is postulated to “decompress” intracompartmental edema in acute muscle compartment syndromes. Animal data support an acute reduction in intracompartmental pressures¹²¹; long-term tissue protection and human outcomes have not been validated. High-dose corticosteroids have been

proposed as a treatment option for refractory cases of rhabdomyolysis but prospective studies are lacking.¹²²

In summary, rhabdomyolysis is a frequent, treatable disorder. Extensive metabolic research has yielded a number of clues about the cause of AKI during rhabdomyolysis. Therapy should emphasize aggressive and early volume resuscitation. Renal replacement therapy may be necessary to assist in managing the metabolic complications of patients; patients have a good prognosis for recovery of rhabdomyolysis-induced AKI.

KEY POINTS

- Populations at risk for hypothermia include the elderly, people with preexisting chronic medical conditions, and people suffering from alcoholism and drug intoxication. Emerging populations include wilderness enthusiasts and winter sport participants.
- All intervals—PR, QRS, and QT—are prolonged secondary to hypothermia-induced slowed impulse conduction through potassium channels.
- Patients with moderate or severe hypothermia should be resuscitated until adequate rewarming is achieved before declaring efforts as unsuccessful.
- The diagnosis of heatstroke should be considered in patients with core body temperatures greater than 41°C.
- Severe dehydration, anhidrosis, and extreme hyperpyrexia are common in external heatstroke.
- Myocardial dysfunction with depression of left ventricular ejection fraction also has been described after heatstroke that resolves with treatment.
- Acute renal failure occurs in up to one third of patients with heatstroke.
- Intravascular volume restoration must be individualized. In general, patients with exertional hypothermia are severely hypovolemic.
- The most effective approaches to lowering the core temperature are immersion and evaporative methods.
- By far, the most important measure for MH is the immediate cessation of any suspected triggering agents.
- NMS is characterized by muscle rigidity and altered mental status, followed by autonomic instability and hyperthermia.
- Dopamine agonists such as bromocriptine, amantadine, and levodopa-carbidopa have been successfully employed in treating NMS.
- Rhabdomyolysis is unlikely to occur with a creatine kinase level below 5000 U/L unless volume depletion or another kidney insult is present.

KEY POINTS (Continued)

- Aggressive volume resuscitation is more important than the type of volume replacement given to reduce the risk of myoglobin-induced AKI in cases of rhabdomyolysis.
- Alkaline-based volume resuscitation may worsen hypocalcemia.
- Rhabdomyolysis-associated AKI, including cases requiring renal replacement therapy, has a good prognosis.

Open Versus Closed Intensive Care Units: Intensivist-Led Model

CULTURE TRANSFORMATION AND ORGANIZATIONAL LEARNING

The delivery of critical care services continues to represent a disproportionate share of health care expenditures relative to the proportion of patients who use these services. The federal Medicare program has become the largest provider of health care insurance in the United States and in 2002 accounted for nearly 30% of annual payments to hospitals.¹ An analysis of Medicare admissions in 2000 determined that cases involving a stay in an intensive care unit (ICU) cost nearly three times as much as those limited to the general care wards. Nevertheless, only 83% of the cost of the care of ICU patients was reimbursed, compared with 105% for patients cared for on the general care floors.² Over the subsequent 5 years, critical care costs reportedly increased another 44%.³

Against this challenging background, ICU administrators must plan for expected needs, improve on the efficiency and quality of care, and adequately staff their organizations. Additional challenges include coping with a pending reduction in the size of the critical care workforce concomitant with an increase in the proportion of patients utilizing these resources. Administrators must respond to pressures from external organizations to meet higher standards of care delivery. These tasks are not insurmountable. The ICU leadership in cooperation with administration is uniquely positioned to respond to these problems. In the ICU, the relatively small number of ICU beds, a compartmentalized physical plant, and the large degree of control that leaders

can exert over the environment make it a fertile ground for change.

Accordingly, the principal consideration for ICU administrators becomes a question of what type of structure and leadership their ICU will need to accomplish its mission. Typically, ICUs have been structured along the lines of tertiary, large community, and small community hospitals. These hospitals have different aims and goals and differing capacities to respond to acuity in the care of patients. Likewise, most ICUs have a designated ICU director with roles and responsibilities commensurate with those goals. Standards of care for typical arrangements have been described in the literature.⁴ An essential function of ICU administration is to determine and specifically articulate the ICU's compliance with these standards.

Once an ICU's structure and leadership are well established, administrators may turn their attention to addressing the challenges presented by economic, market, and technologic forces. Increasingly, well-run ICUs have striven to promote an ICU culture that aims for efficiency while continuously improving the quality of care provided to patients. Performance improvement seeks to integrate best scientific practice into the care of critically ill patients. Regardless of the type of structure and leadership selected for a particular ICU, a focus on quality improvement can optimize function and build efficiencies to care for critically ill patients. Methodologies such as Six Sigma may be useful.

THE PRESENT-DAY CRITICAL CARE LANDSCAPE

Establishing an agenda for administrators and leaders of ICUs starts with a critical analysis of their current position in critical care delivery. This section describes the ongoing evolution of the critical care landscape in regard to patterns of use, costs, and current configurations.

Surveys of critical care delivery in the United States date back to the early 1990s.^{5,6} Reports of the supply and demand of adult critical care were most recently completed in 2000 through a joint effort on behalf of the American Thoracic Society (ATS), the American College of Chest Physicians (ACCP), and the Society of Critical Care Medicine (SCCM).⁷ Estimates on current and future requirements for adult critical care and pulmonary medicine physicians in the United States were reported by the Committee on Manpower for the Pulmonary and Critical Care Societies (COMPACCS). Angus and coworkers, on behalf of the COMPACCS group, extended their inquiry in 2006 to profile the organization and distribution of ICU patients and services in the United States.⁸

The initial COMPACCS study concluded that in 1997, intensivists provided care to 36.8% of all ICU patients and that intensivist level care was more common in regions with high managed care penetration. The 2006 update estimated that there were 5980 ICUs in the United States, caring for approximately 55,000 patients per day. Sixty-five percent of ICUs were combined medical-surgical ICUs; 71% were located in nonteaching community hospitals; and 62% of all ICUs were located in hospitals with fewer than 300 beds. Another important finding was the projected shortfall of critical care physicians of 22% by 2020 and 35% by 2030.

In response to the COMPACCS study report, an analysis was requested by the U.S. Senate. In 2006 a report to Congress from the U.S. Department of Health and Human Services' Health Services and Resource Administration (HSRA) updated the findings in COMPACCS, reiterating their projections with respect to the critical care workforce.⁹ The HSRA workforce analysis indicated that the growth and aging of the population alone will increase demand for adult intensivist services by at least 38% between 2000 and 2020. Similarly, critical care nursing availability remains woefully inadequate to meet the demand. Proactive recruitment and retention strategies are paramount to maintain high-quality nursing care (Box 70.1).

The shortfall in supply of intensivists may drive administrators to consider an alternative critical care delivery team model, which may include nonintensivist physicians and physician extenders. Consideration to hospitalists partnering with intensivists as an option to fill the gap in intensivist supply is being addressed by two task forces, first in a publication of the 2004 Framing Options for Critical Care in the United States (FOCCUS) report and second in 2007 Prioritizing the Organization and Management of Intensive Care Services in the United States (PrOMIS) Conference Report.^{10,11} Reports from these task forces made three recommendations in an attempt to address the situation: to include (1) uniform protocols for intensive care treatment, (2) a process for certification of physicians providing critical care services with a competency assurance process, and (3) health service research with a focus on outcomes of ICU

Box 70.1 Reasons for Nursing Turnover and Retention Strategies

Why Nurses Leave

- Increased market demand
- Heavy workload/inadequate staffing
- Better pay elsewhere
- More flexible scheduling elsewhere
- Better career/developmental opportunities elsewhere
- More desirable work culture elsewhere
- Better benefits elsewhere
- Inadequate managerial skills
- Physician relationships
- Better employer reputation elsewhere

Retention Strategies

- Enhancing supplemental pay plans
- Increasing base pay
- Retention bonuses
- Variable pay/incentives
- Flexible scheduling/shifts
- Addressing staffing needs using rotations/float pools
- Staffing support using unlicensed personnel
- New clinical advancement programs
- Enhanced continuing education
- Regular staff input/surveys
- New processes to assist in delivery of care
- Changing patient care delivery model
- Increasing staff understanding of organizational mission, goals, and initiatives
- Management training/skill building
- Enhancing collaboration with support departments
- Physician relations programs
- New work environment/culture initiatives

(2002, August) Health care at the crossroads: Strategies for addressing the evolving nursing crisis, is a copyrighted publication of Advanstar Communication Inc. All rights reserved.

patients cared for by hospitalists.¹² In another model, use of physician extenders may include physician assistants (PAs) and nurse practitioners (NPs). Limited research exists examining the use of NPs and PAs in the critical care setting with the majority focused on their impact on patient care management. Despite the small sample sizes and limited studies, NPs and PAs have demonstrated enhanced patient flow, improved clinical and financial outcomes for mechanically ventilated patients, reduction in ICU and hospital length of stay, and improved management in the heart failure patient population.¹³ Because the lack of intensivist staffing is unlikely to change significantly over the next few years, alternative models may be on the horizon.

Regardless of the expected reductions in available staffing, calls for increased access to intensivists continue with a goal of increasing intensivist coverage in-house around the clock. Despite the challenge by one recent study,¹⁴ multiple studies have demonstrated mortality rate and cost-savings benefits to critically ill patients receiving care by intensivists. Young and Birkmeyer estimated that in the context of 360,000 deaths occurring each year in ICUs, 54,000 lives

may be saved annually with intensivist staffing.¹⁵ Similarly, Pronovost and colleagues have estimated that more than \$5 billion could be saved annually.¹⁶ A report generated for the Agency for Healthcare Research and Quality (AHRQ) notes that these benefits alone underestimate the potential improvement in the quality of care in terms of fewer complications, avoiding inappropriate utilization, decreased patient suffering, and better end-of-life care.¹⁷

The Leapfrog Group, a consortium of companies that purchase health care for their employees, convened in an effort to leverage their purchasing power to improve the quality of care. This powerful group has focused on improving four key areas central to patient safety and to cost containment in health care: (1) the use of computerized physician order entry, (2) the oversight of critical care physicians in the care of ICU patients, (3) the use of evidence-based hospital referral systems, and (4) Leapfrog safe practice scores.¹⁸ The influence of this group on both payers and health systems alike has contributed to the increasing demand for intensivists to care for critically ill patients. Unfortunately, the 2006 update to the COMPACCS study suggests that this need has gone essentially unmet. Loosely defining Leapfrog-compliant intensivist coverage for 80% of critically ill patients and the presence of 24-hour in-house physician coverage, Angus and colleagues found that only one in four ICUs had 80% intensivist coverage and that half had no intensivist coverage. Very few hospitals provided in-house physician coverage during off hours: 20% during weekend days, 12% during weekday nights, and 10% during weekend nights. Overall, only 4% of adult ICUs in the United States appeared to meet even a liberal interpretation of Leapfrog standards.⁸

IDEALIZED DESIGN FOR CRITICAL CARE PRACTICE

In the face of an emerging demand-driven crisis in critical care, the task of effective ICU administration will only become a more difficult challenge. Nevertheless, efforts must be made to adapt care delivery patterns to the emerging demand crisis. Failure to develop new patterns of critical care delivery will ensure inadequate care for thousands of patients for years to come. In the absence of renewed planning, failure probably will evolve slowly, first affecting vulnerable populations, such as the uninsured and those located in rural areas. As time passes, a larger and larger proportion of Americans will receive less than the ideal standard of care.

A key first step is to halt further deterioration in present practice through effective coordination and communication to mitigate further erosion in practice standards (Boxes 70.2 and 70.3). Strategies to refine critical care delivery and meet predicted needs are present in the literature. Retaining tactics that have proved effective in trauma care are essential in building on current designs to streamline access to critical care. Hospital systems will need to collaborate on the care of critically ill patients in order to distribute critical care equitably as a resource, a social commodity. Finally, a realignment of values among health care leaders to build and reinforce a culture of efficiency, safety, and continuous improvement may stave off mediocrity.

Box 70.2 Examples of Best Practices for Coordinating Care in the Intensive Care Unit (ICU)

Within the ICU

- Specific guidelines and protocols for medical and nursing care
- Physician credentialing for selected procedures (e.g., intubation, invasive monitoring)
- Updated protocols for limiting life-supporting therapy
- Physician rounds made early, facilitating communications and planning by nurses
- Orientation, written guidelines, and close supervision for residents
- Rounds and conferences with pharmacist, dietitian, radiologist
- Emphasis on decentralized services (satellite pharmacy, laboratory, and radiograph viewing) or close to ICU
- Guidelines for nursing change of shift report

Between the ICU and Other Areas

- New nurses oriented to emergency, recovery, step-down units
- Standardized nursing reports for patients transferred from ICU; interunit conferences for long-term, complex cases
- Floor care for hopelessly ill or chronically ventilated patients with a do-not-resuscitate order and other treatment limits
- Direct phone line from visiting area to unit clerk
- Administrative and support services with emphasis on importance of satisfying "internal" customers

From Zimmerman JE, Shortell SM, Rousseau DM, et al: Improving intensive care: Observations based on organizational case studies in nine intensive care units: A prospective, multicenter study. *Crit Care Med* 1993;21:1443.

RATIONAL MODEL FOR CRITICAL CARE DELIVERY

Delivery of critical care should attempt to balance the needs of the community with access to the highest quality critical care services within that area. The American College of Surgeons (ACS) set the precedent for national practice standards for specific sets of critically ill patients when trauma centers were organized. When patients sustain injury with possible trauma, their care is initiated at appropriate trauma centers, depending on readiness and capacity to deliver care. Each designated level of classification (levels I to IV) has associated standards designated by the ACS. The structure has redefined the care of trauma patients and has been associated with improved outcomes and decreased mortality rates.^{19,20}

Advancement in critical care delivery is feasible using a similar approach. The American College of Critical Care Medicine (ACCM) of the SCCM has developed a system to segregate hospitals into specific categories based on readiness and capacity to deliver critical care services (Box 70.4). These guidelines were first published in 1999 and revised in 2003.⁴ Appropriate application of these guidelines provides a gateway in developing collaborative relationships and to ensure a streamlined approach to critical care delivery.

Although the ACCM guidelines set the stage for ideal function of hospitals within each classification, a substantial

Box 70.3 Examples of Best Communication Practices

- Bulletin boards used to highlight important messages
- Communication books for facilitating information transfer
- Regular, consistent staff meetings with a set agenda and staff input
- Brief, group change-of-shift report followed by individual bedside reports
- Nurse manager available to staff through regular visits on all shifts
- Working paging systems; immediate response 24 hours a day, 7 days a week
- Charting systems that are user friendly, clear, and readily available
- Daily rounds promoting high levels of interaction between nurses and physicians
- Multidisciplinary forums for information sharing
- Social workers used to facilitate communication with patients' families
- Open visiting hours for family members
- Rotating shifts for orienting new nurses
- Standard evaluation form for registry/agency nurses

From Zimmerman JE, Shortell SM, Rousseau DM, et al: Improving intensive care: Observations based on organizational case studies in nine intensive care units: A prospective, multicenter study. *Crit Care Med* 1993;21:1443.

performance gap between compliance with the guidelines and actual practice remains. Administrators should define their mission, thereby determining the range of services that their hospital seeks to effectively offer patients. Instrumental aspects to consider include the population the hospital serves, services provided by neighboring hospitals, and subspecialties of the staff physicians. Other factors that may be informative in redesign include a list of common diagnoses and acuity level in patients who are routinely treated.⁴

Even hospitals that appear to have well-integrated strategies can benefit from review of current operating procedures. As part of the overall strategy for evolution of hospitals into this operating model, it is reasonable to expect a large number of hospitals to be in transition at any given time. Resistance to regionalization at the local level can be anticipated. Local hospital administrators will not want to forgo revenue, community physicians will not want to “lose” patients to the referral hospital, and communities may resist loss of local services.

The specific standards that define level I and level II care are summarized in [Box 70.5](#). Many hospitals will not be able to maintain these standards, and overlap with level II or level III critical care facilities may be considerable. Level II hospitals capable of providing comprehensive care for most diagnoses should attempt to emulate the level I guidelines for most conditions. For instance, a level II institution may not have the resources for optimal treatment of severe burns, but that facility may provide excellent surgical, cardiac, and posttransplantation medical care. Such a facility should aim to meet level I standards for conditions other than severe burns.

Box 70.4 Levels of Critical Care

Level I critical care: Level I critical care centers have intensive care units (ICUs) that provide comprehensive care for a wide range of disorders requiring intensive care.⁴ They require the continuous availability of sophisticated equipment, specialized nurses, and physicians with critical care training. Support services including pharmacy services, respiratory therapy, nutritional services, pastoral care, and social services are comprehensive. Although most of these centers fulfill an academic mission in a teaching hospital setting, some may be community-hospital based.

Level II critical care: Level II critical care centers have the capability to provide comprehensive critical care but may not have resources to care for specific patient populations (e.g., cardiothoracic surgery, neurosurgery, trauma). Although these centers may be able to deliver high-quality care to most critically ill patients, transfer agreements must be established in advance for patients with specific problems. The ICUs in level II centers may or may not have an academic mission.

Level III critical care: Hospitals that have level III capabilities have the ability to provide initial stabilization of critically ill patients, but they are limited in the ability to provide comprehensive critical care. These hospitals require written policies addressing the transfer of critically ill patients to critical care centers that are capable of providing the comprehensive critical care required (level I or level II). These facilities may continue to admit and care for a limited number of ICU patients for whom care is routine and consistent with hospital and community resources.

Adapted from Haupt MT, Bekes CE, Brilli RJ, et al: Guidelines on critical care services and personnel: Recommendations based on a system of categorization of three levels of care. *Crit Care Med* 2003;31:267-268.

For level II or III institutions, a critical requirement of the guidelines is to establish agreements for transfer of patients for higher levels of care. It should be a usual practice in such facilities to stabilize patients with the intention to invoke established agreements to transfer to collaborating facilities.²¹ Although completing transfers may be routine for ICU staff, the requirement for agreements established in advance with collaborating institutions to accept transfers may be novel. In order to develop the efficiencies that will be necessary in the emerging critical care environment, these types of prenegotiated arrangements will be necessary to ensure access to needed care.

The requirement to transfer also implies a burden of review on level II and level III centers to understand the treatment options available at more advanced centers with respect to a wide array of diagnoses. Although many administrators may assume that their clinicians maintain a full understanding of treatment options outside their facility, this assumption may be faulty. It is therefore appropriate with respect to specific diagnoses to develop codified procedures that demarcate established points in care suitable for transfer. These procedures may be incorporated as part of the envisioned interhospital agreement to coordinate transfers. Bed availability in the tertiary hospital may require alternative solutions in times of high occupancy.

Box 70.5 Intensive Care Unit (ICU) Leadership

- A. A physician Unit Director is required. In general, the director should meet the guidelines for the definition of an intensivist as published by the Society of Critical Care Medicine. Specific requirements for the Unit Director include:
 1. Training, interest, and time availability to give clinical, administrative, and educational direction to the ICU
 2. Board certification in critical care medicine
 3. Time and commitment to maintain active and regular involvement in the care of patients in the unit
 4. Expertise necessary to oversee the administrative aspects of unit management, including formation of policies and procedures, enforcement of unit policies, and the education of unit staff
 5. The ability to ensure the quality, safety, and appropriateness of care in the ICU
 6. Availability (of either the Director or a similarly qualified surrogate) to the unit 24 hours a day, 7 days a week for both clinical and administrative matters
 7. Active involvement in local or national critical care societies
 8. Hospital privileges to perform relevant invasive procedures
 9. Active involvement as an advisor and participant in the organization of the care of the critically ill patient in the community as a whole
 10. Participation in the education of unit staff, other physicians, house staff, and medical staff as indicated
 11. Participation in scholarly activity (case reports, clinical and basic research)
12. Active participation in the review of the appropriate utilization of ICU resources in the hospital
- B. A Nurse Manager is appointed to provide precise lines of authority, responsibility, and accountability for the delivery of high-quality patient care. Specific requirements for the Nurse Manager include:
 1. An RN with a BSN or preferably an MSN degree
 2. Certification in critical care or equivalent graduate education
 3. At least 2 years of experience working in a critical care unit
 4. Previous management experience, including experience with health information systems, quality improvement, risk management activities, and health care economics
 5. Preparation to participate in the on-site education of critical care unit nursing staff and physicians-in-training
 6. Ability to foster a cooperative atmosphere with regard to the training of nurses, physicians, respiratory therapists, and other personnel involved in the care of critical care unit patients
 7. Regular participation in ongoing continuing nursing education
 8. Ability to participate in, and foster cooperation for, scholarly activity in the ICU (e.g., presentations, clinical research)
 9. Knowledge about current advances in the field of critical care nursing
 10. Participation in strategic planning and redesign efforts

From Haupt M, Bekes CE, Bayly RW, et al: Critical care services and personnel: Recommendations based on a system of categorization into two levels of care. American College of Critical Care Medicine of the Society of Critical Care Medicine. Crit Care Med 1999;27:422.

Committing the national critical care infrastructure to reorganization in line with the ACCM guidelines will not shield critical care providers and their patients from evolving demographic and market forces. However, by advancing institutions' understanding of their own critical care infrastructure, needs, and capacity, and by establishing agreements for transfer between hospitals, the initiative will facilitate the movement toward regionalization of care. A study commissioned by the SCCM in 1994 suggested that regionalization of critical care services probably is beneficial to patients, in part by promoting access to larger academic institutions and resources, increasing subspecialty availability, and providing expertise in the care of the critically ill.²²

In trauma systems, studies suggest that considerable efficiencies have been obtained with regionalization. Both mortality rates and hospital lengths of stay have decreased.^{19,23} Transition to level I ACS status has incurred increased costs at some centers, whereas other centers indicate that certification reduced costs.^{24,25} Beyond the financial impact of regionalization, the transition to a regional trauma system has promoted interhospital cooperation and promoted more effective resource utilization.^{26,27}

FINANCIAL MODELING OF CRITICAL CARE

The need for a transition to more rational structures in the provision of critical care services implies that hospitals will require an accurate accounting of costs and revenues as

changes are made. Additionally, ICU quality improvement programs rely on an accurate understanding of costs to measure benefit (or harm) from programs intended to improve the quality of care. Several financial models exist to assess costs in the ICU.^{28,29} A given hospital's cost accounting system may determine whether the ICU is viewed as generating a profit or a loss. Traditional methods have focused on the ICU as a cost center but not as a venue that may be revenue generating.³⁰ Even in cases in which an ICU may always represent a net loss of revenue for an institution, understanding the revenue streams can permit optimization and diminish losses.

STATE OF CRITICAL CARE REIMBURSEMENT

The federal Healthcare Financing Administration, which formerly administered Medicare and Medicaid, was renamed in 2001 the Centers for Medicaid and Medicare Services (CMS). Data from CMS's Medicare Provider Analysis and Review (MEDPAR) database remain the single best public source to support understanding of the financial horizon for hospital administrators. Contributing 30% of annual payments to hospitals in 2002, Medicare is the single largest payer in the U.S. health care system.¹

Using the MEDPAR database, Cooper and Linde-Zwirble analyzed all hospital admissions during 2000 to determine

the incidence, cost, and payment for ICU services.² Their findings suggested that more than one fifth of all Medicare cases had an ICU stay with a cost to hospitals of nearly three times as much as floor patients—\$14,135 versus \$5571. However, ICU cases were paid at a rate only twice that of floor cases—\$11,704 versus \$5835. This means that only 83% of costs were paid for ICU patients, compared with 105% for floor patients, generating an annual \$5.8 billion loss to hospitals when ICU care is required.

Halpern and Pastores describe recent patterns of critical care medicine (CCM) use and costs in the United States from 2000 to 2005. The study analyzed data from the Hospital Cost Report Information System. Results indicate the number of acute care hospitals decreased by 20.6%, hospital beds decreased by 4.2%, yet CCM beds increased by 6.5%. Fifty-two percent to 56% of insurance coverage is attributed to Medicare and Medicaid for both CCM and hospital days. Data show that the critical care payer mix is evolving with an increase in Medicaid recipients using CCM services. The results show the percentage of CCM days by Medicare decreased by 3.8% compared to an increase of 15.5% by Medicaid. From 2000 to 2005 the CCM cost per day rose 44.2% (from \$2698 to \$3518). With an increase in uninsured and underinsured, development of a plan to understand the impact of the Medicaid population should be considered during strategic planning.³

FOCUS ON EXPENDITURES AND REVENUES

In view of the dramatic overall losses that hospitals sustain relative to expenditures on critical care patient services, a natural instinct among ICU administrators is to cut costs by reducing services. Hospital costs are best analyzed as either fixed or variable costs and as either direct or indirect expenditures. Fixed costs represent expenditures related to buildings, equipment, and certain labor costs; variable costs include items dependent on the volume of hospital operations, such as pharmaceutical expenditures and patient care supplies.

Reducing services is a flawed method to contain costs, however, because the fixed costs (and some variable costs) associated with the provision of critical care remain high and the differential savings achieved by limiting access to these services is small. Typically, direct patient care costs can be accounted to individual patients whose care generated those costs, and indirect patient care costs are averaged across all patients admitted to critical care. The indirect costs are not reduced when access to available services is limited. Reliable savings stem from elimination of services, rather than limiting access to or frequency of utilization of services.³¹

Moreover, the availability of sufficient services to care for the population at large remains essential. In line with the need to develop a more rational distribution of critical care delivery as outlined earlier, eliminating unnecessary services due to duplication in the community is appropriate. Once unnecessary or underutilized services have been eliminated, the next most appropriate steps to maximize ICU efficiency involve turning attention away from cost-cutting measures and toward revenue-enhancing strategies.

The development of cost-cutting methods may be further understood in evaluating the various regions of the United

States in overall spending differences. Data from the Dartmouth Atlas Project in five U.S. hospital regions from 1992 to 2006 found annual Medicare spending growth rates range from 2.3% to 5% per capita.³² Understanding this wide range in expenditures in areas with similar technologic and health care access may influence regions/hospitals with higher spending to develop more efficient and effective services.

CRITICAL CARE AS A PRODUCT LINE

Organizing a business plan for the critical care division, Bekes and colleagues³⁰ isolated the major sources of critical care patients and their relative profit or loss for the division. Analysis via the customary cost accounting methods employed by the hospital demonstrated hospital-to-hospital transfers appeared to produce a majority of the revenue. Focusing on this source of revenue as a unique “product line” enabled these clinician-investigators to promote these services more widely in the surrounding community.

Viable “products” may vary from institution to institution. Factors that may influence whether a particular service offered by the ICU is profitable or not include the availability of critical care resources in the community, the presence or absence of a stable network of hospitals for referrals, and the organizing structure of the institution (academic versus community, tertiary care versus otherwise, and so on). Presuming that the gap in reimbursement for critical care services noted in the Medicare data reflects patterns from other payers, many institutions may not be able to demonstrate a profit from their ICU regardless of identifiable sources of revenue. Nevertheless, in order to stave off losses of even greater magnitude, efforts to identify sources of revenue within critical care units will be essential as the health care market evolves.

CRITICAL CARE QUALITY IMPROVEMENT

Several market forces, as described earlier, in combination with clinicians’ drive to provide the best possible care for ICU patients in a safe environment, have created a standard in critical care delivery: quality improvement. Although quality improvement in health care may not seem novel to practitioners involved in the day-to-day delivery of critical care, the field, much like critical care as a specialty, is relatively new. Many organizations and participants have begun to outline the scope of the field, but at present the boundaries of critical care quality improvement are defined only by a consensus of the involved parties. Critical care quality improvement initiatives are less than reified, however, and they are increasingly becoming the lens through which many intensivists view their daily work in the ICU.

BACKGROUND

In 1999, the Institute of Medicine (IOM) of the National Academies published a landmark report, *To Err Is Human: Building a Safer Health System*. The National Academies bring together committees of experts in all areas of scientific and technologic endeavor to address critical national issues and give advice to the federal government and the public. The

IOM report was widely hailed as groundbreaking in view of its documentation of the ways in which the health care system harms patients. Some of the findings about the American health care system included the following: (1) tremendous gaps exist between medical knowledge and practice; (2) adverse events harm patients far too often; (3) too many people do not get the care they need; and (4) the system propagates waste by permitting fragmentation of care and utilization inefficiencies.³³ In *To Err Is Human*, the IOM also estimated that despite incurring costs that are 40% greater than those for the next most expensive nation in terms of health care, 44,000 to 98,000 Americans die each year as a result of errors in their health care.

In 2003, in an exhaustive review of nearly 7000 patient charts across all regions of the United States, McGlynn and colleagues reported that the average defect rate, defined as the percent of cases in which care consistent with 439 indicators of quality was not delivered, approached 45% nationally.³⁴ Stated otherwise, patients receive the care indicated slightly more than one half of the time. These investigators concluded that the deficits identified in adherence to recommended processes for basic care posed a continuing immediate danger to the health of the American public.

DONABEDIAN FRAMEWORK

Building on work begun by Donabedian, the IOM published *Crossing the Quality Chasm: A New Health System for the 21st Century* in 2001. The report outlined fundamental changes that must be made in order to improve health care in the United States. Donabedian had described three components of quality care—structure, process, and outcome—each of which must be addressed to effectively control and manage quality in health care settings.³⁵ He proposed that each overarching concept of control should be monitored using specific tools (Table 70.1). The IOM report also refined Donabedian's seven attributes of high-quality health care, proposing instead six primary aims: safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity.³⁶

QUALITY IMPROVEMENT LANDSCAPE

Based on formidable critiques of the quality of the U.S. health care system, a variety of organizations either willingly

have taken up the challenge to improve health care or, through legislation, have been empowered to improve the delivery of health care in the United States. All of these efforts have led to creation of agencies or activities with relevance to the ICU.

AGENCY FOR HEALTHCARE RESEARCH AND QUALITY

Funding for health services research is achieved primarily through grant applications to the AHRQ. Lucian Leape and Donald Berwick report that the Center for Quality Improvement and Safety, a division of AHRQ, has emerged as a leader in education, training, convening agenda setting workshops, disseminating information, developing measures, and facilitating the setting of standards.³⁷ AHRQ supports and funds efforts to evaluate best practices, medical errors, and development of patient safety indicators. The agency also has articulated an agenda that promotes the advancement of evidence-based best practices.

In 2001, Congress appropriated \$50 million in annual funding for general patient safety research through AHRQ. Within 3 years these funds were assigned to an information technology focus. Leape and Berwick, key health care quality opinion leaders, lamented that this initial funding and subsequent reversal both legitimized health services research and at the same time starved these new researchers of the ability to undertake additional efforts.³⁷ Although investigator-initiated research funding has declined, the previous work of sentinel studies has changed the face of health care. AHRQ's funding in 2009 was allocated to compare alternative treatments for health conditions, reduce threats to patient safety, and advance health information technology.³⁸

NATIONAL QUALITY FORUM

The National Quality Forum (NQF) has maintained close alignment with the platform advanced by the AHRQ. The NQF is a private, not-for-profit membership organization created to develop and implement a national strategy for health care quality measurement and reporting. The group seeks to improve American health care through endorsement of consensus-based national standards for the measurement and public reporting of health care performance data. Working with a broad base of health care interests including governmental agencies, insurers, and various medical associations, the NQF has prevailed upon hospitals to report compliance rates with their measures. In 2002 the NQF published a list of 30 evidence-based best practices ready for implementation. This list of practices was expanded in 2005.

THE JOINT COMMISSION

The Joint Commission (JC), formerly the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), evaluates and accredits nearly 15,000 health care organizations and programs in the United States. The Commission, commonly misunderstood to be a governmental agency, is an independent not-for-profit organization. This body seeks to continuously improve the safety and quality of care provided to the public through the provision of health care accreditation and support for services that foster performance improvement in health care organizations.³⁹

Table 70.1 Relations Between Quality Areas and Management Tools with Their Relative Importance

Quality Area	Management Tools		
	Standards	Guidelines	Indicators
Structures	+++	+	+
Processes	++	+++	++
Results/outcomes	+	++	+++

Reproduced from Frutiger A, Moreno R, Carlet J, et al for the Working Group on Quality Improvement of the European Society of Intensive Care Medicine: A clinician's guide to the use of quality terminology. *Intensive Care Med* 1998;24:860-863.

In 2003, after NQF's publication of evidence-based safe practices, the JC required hospitals to implement 11 of these practices.⁴⁰ The JC also has taken a special interest in developing a set of ICU core measures that are at present part of its library of supplemental measures.⁴¹ Reserve measures, unlike the core measures previously proposed by the JC to satisfy its ORYX* performance measurement requirements for accreditation, are available for hospitals that are seeking a set of voluntary measures to monitor ICU care.

The ICU JC reserve measures included six measures:

- ICU 1: Ventilator-associated pneumonia (VAP) prevention—patient positioning
- ICU 2: Stress ulcer disease (SUD) prophylaxis
- ICU 3: Deep vein thrombosis (DVT) prophylaxis
- ICU 4: Central line-associated bloodstream infection (CLABSI) rate
- ICU 5: ICU length of stay, risk-adjusted
- ICU 6: Hospital mortality rate for ICU patients, risk-adjusted⁴²

Reporting of the JCAHO ICU core measures was stopped July 1, 2005, after a decision was taken to align the measure set with those under development at CMS and a new entity, the Surgical Care Improvement Project (SCIP). SCIP is a collaboration among CMS, the Centers for Disease Control and Prevention (CDC), and more than 20 surgical organizations. Under this arrangement, JCAHO has agreed to refocus the ICU reserve measures to apply primarily to surgical care. Ultimately, once these standards are evaluated and approved through the NQF consensus process, they will satisfy ORYX performance measurement standards.⁴³

ALIGNMENT OF EFFORTS

The alignment of forces interested in promoting evidence-based standards of care has led to efforts to establish a single set of applicable measures for hospitals. Although NQF appears to remain the ultimate clearinghouse for the endorsement of national standardized measures, the Hospital Quality Alliance (HQA) has been instrumental in decreasing fragmentation in the development of national measures for quality of care. The HQA is a public-private collaboration including the CMS, the American Hospital Association, the Federation of American Hospitals, and the Association of American Medical Colleges. The HQA is supported by the AHRQ, NQF, JCAHO, American Medical Association, American Nurses Association, National Association of Children's Hospitals and Related Institutions, Consumer-Purchaser Disclosure Project, AFL-CIO (American Federation of Labor and Congress of Industrial Organizations), AARP, and U.S. Chamber of Commerce.⁴⁴

THE LEAPFROG GROUP: PURCHASERS AND PAYERS

The Leapfrog Group is a coalition of more than 160 large private employers and public purchasers that joined in 2000 to obtain leverage in health care purchasing decisions for employees. The group aims to "leapfrog" over key barriers

as goals of their purchasing directives in order to overcome the poor value in the health care marketplace.⁴⁵

Leapfrog relies on a survey of hospital quality and safety to inform its leadership about adherence to Leapfrog standards nationally. Completion of the survey is voluntary; however, it is required for certification of Leapfrog compliance.

THE INSTITUTE FOR HEALTHCARE IMPROVEMENT

The Institute for Healthcare Improvement (IHI) is a not-for-profit organization with the self-declared aim of leading the improvement of health care throughout the world. Founded in 1991, the IHI has as its mission the acceleration of change in health care by cultivating promising concepts for improving patient care and turning those ideas into action. The IHI has championed the use of collaborative methods to produce improvement in health care.

The IHI launched the 100,000 Lives Campaign in 2004 to reduce mortality rate in hospitals throughout the United States. Accomplishments in the campaign prompted the 5 Million Live Campaign over a 2-year period, 2006 to 2008. The aim of the campaign was to reduce morbidity and mortality rates by taking steps to reduce harm and death. More than 2000 facilities committed to pursue 12 interventions to reduce infection, surgical complication, medication errors, and other areas of unreliable care. One of the interventions included recruiting hospital boards to support the process for improvement in care.

Campaign results include 65 hospitals reporting close to a year or more without a VAP and 35 hospitals close to a year or more without a CLASBI. Success across states includes a reported 42% reduction in CLASBI and a 70% reduction in pressure ulcers in 150 organizations across New Jersey.⁴⁶

SPONSORED STATEWIDE AND INTEGRATED HEALTH SYSTEM COLLABORATIVES

As a national quality agenda has become better articulated, several critical care quality improvement projects have emerged at the state level. In Michigan, for instance, the Michigan Health and Hospital Association's (MHA) Keystone Center for Patient Safety & Quality was created in March 2003. In collaboration with patient safety experts at Johns Hopkins University, MHA launched Keystone: ICU, which enjoys the participation of at least 120 ICUs and 70 hospitals. Johns Hopkins University and MHA estimate that the Keystone: ICU project saved 1574 lives, more than 84,000 ICU days, and greater than \$175 million.^{47,48} This initiative has been expanded to other states such as New Jersey and Rhode Island. Group purchasing organizations such as Veterans Health Administration (VHA) and Premier, Inc. have launched similar national initiatives in critical care quality improvement available to their membership.

PAY FOR PERFORMANCE AND QUALITY REPORTING

Agencies dedicated to critical care quality improvement have had a significant interest in linking quality of care to pay-for-performance. The concept is not a new one as private and public insurers, health care purchasing organizations, and quality improvement thought leaders have

*ORYX is the name of the Joint Commission's initiative to integrate performance measures into the accreditation process. It is not an acronym but was chosen because it was viewed as a unique catchword taken from the name of a graceful, swiftly moving animal.

pressed for the establishment of pay-for-performance plans to drive the market toward meeting evidence-based standards.^{49,50} Although guidelines were established to ensure the fairness of pay-for-performance plans, most recognize the inevitable increase in such initiatives.^{51,52}

Pay for performance has been variously described. One iteration refers to direct payments to physicians from hospitals, or less commonly from insurers, as a reward for high-quality performance. For example, the most recent general practitioner contract in the United Kingdom includes 146 performance measures across seven areas of practice. This contract rewards performance in accordance with the measures with financial incentives.⁵³ First-year results were recently reported: physicians exceeded projections of their performance and achieved a mean of 91% compliance with clinical guidelines. This resulted in payments estimated at \$700 million more than expected.⁵⁴ Despite the seeming success of this program, there is no means to detect whether physicians' compliance efforts also may have detracted from quality in unmeasured patterns of care.⁵⁵

Although pay for performance can contribute to improvements in quality of care it may present ethical concerns, whereby clinicians may become focused on scores and the need to meet the quality measure and potentially lose sight of the whole patient.⁵⁶ Consideration of plans toward minimizing potential harm through quality measures and public reporting may likely contribute to the transition from quality to payment. Maximizing the CCM team efforts in proactive quality improvement initiatives may be the most effective approach to capitalize on making overall care better.⁵⁷

SPECIFIC QUALITY IMPROVEMENT INTERVENTIONS IN CRITICAL CARE

Several intervention-specific quality improvement initiatives in critical care have emerged in the past decade. Many organizations have committed resources to implement such initiatives based in part on high-profile campaigns to improve care and new regulatory or accreditation standards. Some of the strategies for ICU quality improvement benefit from standardized measures available through the NQF and others; however, as practitioners take notice of the growing imperative to change the way critical care is delivered, many cutting-edge initiatives are moving forward without a consensus on which quality indicators should be applied. Often, specific interventions are coupled to strategies that advance more general goals such as developing a culture of safety in the ICU to prevent harm.

SHEWART MODEL FOR PROCESS IMPROVEMENT

Critical care quality improvement initiatives typically have been executed in the setting of collaborative efforts as initially championed by the IHI and adapted by other groups. The precise mechanisms of implementation for these initiatives vary, but most sponsored quality improvement initiatives encourage the use of small-scale experiments to test new ideas. The principle calls for organizations to make the process of scientific prediction a part of routine work and was first advanced in 1931 by Walter Shewart, a pioneer in industrial quality control. Shewart advocated the use of iterative "plan-do-check-act" (PDCA) cycles to systematically

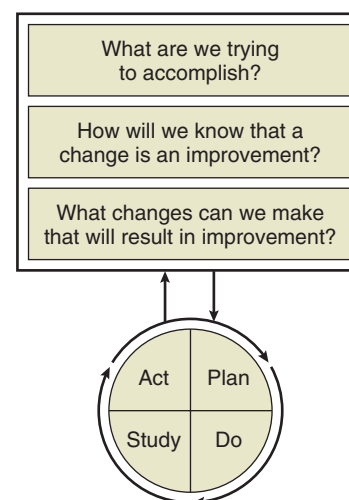

Figure 70.1 Institute for Healthcare Improvement model for quality improvement. (From Langley GL, Nolan KM, Nolan TW, et al: *The Improvement Guide: A Practical Approach to Enhancing Organization Performance*. San Francisco, Jossey-Bass, 1996.)

test new ideas, evaluate their results, and, if successful, implement them.⁵⁸ More recently, the IHI has advocated a similar structure known as the Model for Improvement⁵⁹ (Fig. 70.1).

DECREASING VENTILATOR-ASSOCIATED PNEUMONIA RATES

Reducing mortality risk due to VAP requires an organized process that guarantees the early recognition of pneumonia along with the uniform and consistent application of the best evidence-based practices. Despite variability in clinical definitions to establish valid criteria to diagnose VAP, institutions have devoted considerable effort to combating VAP rates. The most recent evidence suggests the selection of diagnostic criteria may be irrelevant to outcomes. The CDC, however, has offered a clinical definition of VAP that has been widely adopted by the quality organizations cited earlier.⁶⁰

The prototypical collaborative effort to decrease VAP rates has been use of the "ventilator bundle" promulgated by the IHI. The IHI ventilator initiative was initially launched to describe a pattern of best practices for ventilated patients, not to decrease VAP rates. A careful review of the literature on the care of ventilated patients produced four well-evidenced recommendations: elevation of head of the bed to 30 degrees, provision of a daily awakening or "sedation vacation," application of DVT prophylaxis, and provision of peptic ulcer disease prophylaxis. Although not components of IHI's ventilator bundle, several other practices with varying supporting evidence have become commonly applied as well, including the use of oral care techniques and subglottic suctioning.

Between July 2002 and January 2004, multidisciplinary improvement teams from 61 health care organizations participated in an IHI collaborative that included use of the ventilator bundle. Thirty-five of these teams consistently collected data on ventilator bundle element adherence and VAP rates. An average 44.5% reduction in the incidence of VAP was observed in these groups.⁶¹ Sixteen units were

medical-surgical ICUs, in which the average VAP rate decreased from 5.5 to 2.7 cases per 1000 ventilator days.⁶¹ By comparison, the nationwide VAP rate for medical-surgical ICUs reported by the CDC for the January 2002 to June 2003 period was approximately 6.0 per 1000 ventilator days.⁶²

DECREASING CENTRAL LINE-ASSOCIATED BLOODSTREAM INFECTION RATES

In an effort similar to that for decreasing VAP rates, decreasing CLABSI has been a national priority in critical care quality improvement. The CDC has produced a standard measure that defines prevention of these infections as part of the National Healthcare Safety Network's (NHSN) patient safety component protocol.⁶⁰

A typical approach to preventing CLABSI has been advocated by the IHI and includes four elements of care: proper hand hygiene, use of chlorhexidine for skin antisepsis, routine application of maximal barrier precautions, and optimal site selection. In 2004, Berenholtz and colleagues reported that in using a similar strategy, the rate of CLABSI fell from 11.3 to 0 per 1000 catheter days.⁶³ These results were estimated to have prevented 43 catheter-related bloodstream infections, 559 additional days in the ICU, and 8 deaths.⁶³ Cost savings were estimated to be \$1,824,447.⁶³

DEPLOYING RAPID RESPONSE TEAMS

The rapid response team (RRT)—sometimes referred to in the literature as a medical emergency team (MET)—is a team of nurses and other health care professionals (respiratory therapists, pharmacists, emergency department personnel, and others) who bring critical care expertise to the bedside. The teams may or may not include physicians. The essential concept is intervening to prevent harm when nursing staff is urgently concerned about a patient's well-being. The key goal is to act before "failure to rescue" occurs and a patient has suffered a cardiac or respiratory arrest.⁶⁴

The evidence supporting RRT adoption is mixed. Nevertheless, many hospitals have detected the need to have such a team to respond to urgent patient issues when physicians or housestaff may not be readily available. Several facilities that have implemented RRTs have reported a reduction in cardiac arrests and deaths, as well as a reduction in ICU and hospital bed days among survivors of cardiac arrest.⁶⁵⁻⁶⁷ Despite these findings, a single comprehensive negative trial has been published on the effects of MET/RRTs. Eleven hospitals functioned as usual, and 12 introduced a MET system. The investigators concluded that although the introduction of the MET system led to an increase in calls to the team, it did not substantially affect the incidence of cardiac arrest, unplanned ICU admissions, or unexpected death.⁶⁸

RESUSCITATION AND TREATMENT FOR SEVERE SEPSIS OR SEPTIC SHOCK

Unique among projects to improve the quality of care for critically ill patients, the Surviving Sepsis Campaign (SSC) was formed in 2003 with the joint cooperation of the SCCM, the European Society of Intensive Care Medicine (ESICM), and the International Sepsis Forum (ISF). Evidence-based guidelines for the treatment of severe sepsis and septic shock were published in 2004 with an updated version published in 2008 and a second revision scheduled for publication in early 2012.^{69,70} Partnering with the IHI, the SSC

transformed into a global performance improvement program to extend the campaign guidelines to the bedside.⁷¹ The campaign included the development of sepsis bundles, educational material, recruitment of sites and local physician and nurse champions, launch meetings, and a secure database for data collection and outcome measures. Campaign results from 15,022 subjects at 165 international sites report a significant increase in bundle compliance and unadjusted mortality rate decrease from 37% to 30.8% over a 2-year period.⁷²

ESTABLISHING MULTIDISCIPLINARY ROUNDS

Multidisciplinary rounds enable all members of the team caring for critically ill patients to come together formally and offer their expertise as cases in the ICU are reviewed. Multidisciplinary rounds have been established in critical care units with various structures, either nurse-led or physician-led, meeting daily or regularly during the week.

Experience with applying multidisciplinary rounds suggests that although initial meetings may be wide-ranging and unstructured, they can become a vital adjunct to patient care. Specifically, they provide an opportunity for disciplines to share their knowledge of patient care needs and focus the entire care team on common goals. Surveys of institutional perceptions of the state of safety in ICUs have led to the establishment of multidisciplinary rounds.⁷³ These rounds are a mainstay of the effort to change the culture of ICUs from compartmentalized care based upon a single discipline's knowledge to a more holistic approach integrating the talents of the many services caring for critically ill patients.⁷⁴

ASSESSING DAILY PATIENT GOALS

Daily goals assessment allows all parties involved in the care of patients to formally keep track of plans established on either patient care rounds or multidisciplinary rounds and to verify their completion. This typically has been achieved in critical care units by using a daily goals worksheet completed by the rounding team.

One such tool was evaluated by Johns Hopkins University, the VHA, and the IHI in a prospective study. The tool was designed to facilitate explicit communication in the ICU, allow for independent redundancy to monitor key practices, empower nursing to carry out clear plans, increase nurse morale, and avoid duplicate work. The worksheets aimed to reduce ICU length of stay and mortality rate while increasing the care team's understanding of the daily goals for patients in the ICU. In addition, the worksheets were used to document specific items that must be accomplished for patients to leave the ICU; to identify the greatest safety risk to a particular ICU patient; to institute a reminder system that identifies key processes for patients on ventilators; to document the scheduled laboratory tests for a patient; to compile information about the age, number, and sites of catheters; and to organize daily work flow to include communication with the family.

All patients admitted to a 16-bed surgical oncology ICU were eligible for inclusion. The outcome variables assessed were ICU length of stay and percent of ICU residents and nurses who understood the goals of care for patients in the ICU. Baseline measurements were compared with measurements of understanding after implementation of a daily

goals form. At baseline, less than 10% of residents and nurses understood the goals of care for the day. After implementing the daily goals form, greater than 95% of nurses and residents understood the goals of care for the day. After implementation of the ICU Daily Goals Worksheet, ICU length of stay decreased from a mean of 2.2 days to 1.1 days.⁷⁵

PRACTICE MANAGEMENT-CLINICIAN-FAMILY COMMUNICATION

Protocols, guidelines, and toolkits have improved process and outcomes in numerous areas of critical care. Application of these techniques to advance communication with family members of the critically ill are interdependent upon a partnership between clinicians and family members, which is frequently not a recognized goal.⁷⁶ Discussions with family members geared toward establishing treatment goals are important in promoting patient-family-centered care.

Clinician-family meetings are intended to share information related to the patient condition and prognosis and for the family to discuss care preference, family concerns, and goals of treatment.⁷⁷ Early effective communication with patients and family members is imperative in shared decision making as they are an integral part of the care in the critically ill.

The American College of Critical Care Medicine Task Force 2004 to 2005 recognized the need for clinicians to develop a care plan and partner with patients and family members to improve outcomes.⁷⁸ Family members often act as surrogate decision makers for the critically ill, which has been reportedly linked to anxiety, depression, and fatality. Methods to decrease stress include clinicians adapting to the family preference in decision making using a stepwise approach progressing toward improved decision making for the critically ill patient.^{76,79}

Clinician-family conferences should be conducted within 72 hours of ICU admission. Preconferences have been suggested to improve the family experience with future conferences. Increased family satisfaction has been reported when clinicians spend more time listening than talking. Clinical-family communication has been summarized in a mnemonic and used as a framework for communication (Box 70.6). As part of an interventional study reported by Lautrette and associates, application of the VALUE

conference approach resulted in significant reduction in family symptoms of anxiety, depression, and posttraumatic stress disorder 90 days after the patient's death.⁸⁰ Use of printed information, staff champions, and consulting services are necessary resources to facilitate intensive communication.⁸¹ Documentation of the pertinent conference details and treatment goals are essential to assist future clinician-clinician and clinician-family communication throughout the patient's ICU and hospital stay.

OPEN VERSUS CLOSED INTENSIVE CARE UNITS: INTENSIVIST-LED MODEL

A prime example of a structural change (as in the Donabedian model described earlier) that may lead to improvement in the quality of care includes the establishment of an intensivist-led ICU service in medical ICUs. Although in other ICUs, such as neurosurgical units or pediatric units, it is commonly expected that the attending physician is an intensivist trained in that specialty, this has not been the rule in medical ICUs. Typically, mixed medical-surgical ICUs in the United States are "open" in that any physician on staff may admit patients to the ICU and write orders for care of that patient. A recent well-developed literature suggests that "closed" ICUs in which only medical intensivists care for medical patients may be associated with decreased morbidity and mortality rates and length of stay.⁸² Reorganizing ICU physician services in one organization by implementing an intensivist infrastructure has resulted in a 14% absolute risk reduction in mortality.⁸³

Despite these findings, a number of barriers exist to adopting a "closed" model of care. These include excess inpatient bed capacity; reimbursement strategies that provide an incentive for nonintensivists to stay involved in ICU care; internal political barriers among the medical staff that hamper closure; and the growth of the hospitalist movement and an associated unwillingness to relinquish control of patients when admitted to the ICU. Some intensivists have adopted a "consultative" model, rather than providing 24-hour patient coverage.⁸⁴

CULTURE TRANSFORMATION AND ORGANIZATIONAL LEARNING

The ultimate goal of clinical quality improvement work of any sort remains that of creating a culture of enduring change that can absorb new initiatives and sustain gains earned in prior improvement efforts. Underscoring the long-term strategy of ICU culture change in describing improvement initiatives cannot be overestimated. If insufficient attention is paid to the context in which improvement efforts are set into motion, an environment unfamiliar with testing changes and hostile to deviations from routine will frustrate the project itself. To this end, as clinical initiatives are advanced, concern must be maintained for executing projects so as to encourage collaboration and cooperation among the persons who work in the ICU. Typically, these strategies involve crafting of change teams, devising and testing protocols to incorporate the concerns of the front-line users of the protocols, and adapting to local cultural needs and traditions while bringing in new ideas. In the

Box 70.6 Value: A Five-Step Approach to Improving Communication in Intensive Care Unit with Families of Deceased Patients

- V** Value and appreciate statements by family members.
- A** Acknowledge family emotions.
- L** Listen to the family.
- U** Understand who the patient was as a person.
- E** Elicit questions from the family.

From Lautrette A, Darmon M, Megarbane B, et al. A communication strategy and brochure for relatives of patients dying in the ICU. *N Engl J Med* 2007;356:469-478.

course of this work, colleagues cease contemplating their work as discrete projects that can be finalized. Instead, they learn to constantly revise protocols and strategies in response to feedback from the front-line users. If these ideals are maintained in the rollout of key initiatives and structural changes, often a change in mindset from an organization of independent actors to one in which collaborative efforts promote organizational learning can take hold. Unfortunately, to make these cultural transformations gracefully, no scientific procedure is available that can guide the way. The talents of committed and patient people are essential.

KEY POINTS

- Critical care represents a disproportionate share of health care expenditures relative to the proportion of patients who access these services.
- Demand for critical care physician and nursing care will exceed supply in the next 20 years, prompting novel critical care team models.
- Administrative solutions to an emerging critical care crisis are possible and rely on efficiencies that may be obtained in care delivery.
- Market forces and clinicians' drive to provide the best possible care for ICU patients have created a new standard in critical care delivery: quality improvement.
- Multiple interventions have been identified to reduce mortality risk in critical care patients but require consistent performance.
- Optimizing clinician-patient-family communication includes a family meeting within 72 hours using a stepwise approach toward achievement of patient-family-centered goals.

RESPONSE TO DISASTERS

Critical illnesses and the interventions necessary to address them pose many ethical dilemmas for clinicians. Therefore, it is not surprising that critical care physicians encounter ethical dilemmas more often than do general internists.¹ The most frequent predicaments relate to end-of-life care, including decisions about termination of medical treatment, respect for patient autonomy, and conflicts among various parties involved in patient care. Less frequent quandaries stem from concerns about equitable use of resources, truth telling, religious and cultural differences, and professional conduct. On rare occasions, critical care providers must be prepared to address the extraordinary demands related to disasters because the skills and resources at their command offer key components of a well-organized disaster response.

The first section of this chapter focuses on ethical considerations in the everyday operation of the intensive care unit (ICU). The second section discusses the difficult ethical issues involved in decisions at the end of life. The third section discusses ethical questions involved in research in the ICU. Clinical practice and clinical research are

fundamentally distinct enterprises, with different aims and different ethical requirements. In research, the interests of the patient are not the sole priority; but at the same time, the human subjects of ICU research must be protected. The chapter concludes with brief consideration of the ethics of disaster response.

THE DOCTOR-PATIENT RELATIONSHIP

Critical illness stresses the relationship between patients and hospital staff members caring for them. Patients with life-threatening illness often are frightened and feel isolated. Physicians and nurses often must make crucial decisions quickly and despite uncertainty about the consequences of various options. In addition, key decisions frequently must be made while patients are cognitively impaired or unable to communicate. Thus, a combination of the disease process and medical interventions often deprives patients of the power to control their lives.

As a rule, clinicians should follow the same ethical guidance in critical care situations as in less stressful contexts:² They should treat patients with respect. They should deal honestly with patients and should not reveal confidences entrusted to them, unless the well-being of others is threatened. They should act in good faith, keep promises and commitments, and try faithfully to meet fiduciary responsibilities to patients.

At the same time, ICU staff must balance competing moral obligations that may limit or override obligations to fidelity to one particular patient, such as the needs of other patients who are currently under their care or may need their care in the future. Various models of decision making have been proposed—ranging from an *informative* model, in which patients make the decisions quite independently after the clinician has offered sufficient information, to a more *paternalistic* model, in which clinicians make decisions based on their judgment of what is in the best interest of the patient.³ A commonly accepted model today is a *deliberative* model, in which the clinician gives the patient information about his or her condition and the medical options, along with their advantages and disadvantages, and the patient explains his or her values and preferences, and together they reach a treatment decision. This model must be adapted to the extreme circumstance of critical illness.^{4,5} Leaders in the field of critical care medicine have endorsed a model of decision making, shared decision making, that recognizes that patients and their surrogates will vary in their desire to participate in decision making, but generally all will feel most comfortable with decisions if they have been given sufficient information to be able to understand and trust the decision process.⁶⁻⁹

Clinicians in the ICU should assess each patient's cognitive ability, provide information, and involve the patient or the patient's family in decisions about his or her treatment to the extent feasible.

Most physicians do not follow the same model with every patient or in every encounter. Regardless of the model adopted, clinicians should heed the elements of good ethical practice when making their decisions (Box 71.1). ICU clinicians also should be attentive to the many facets of patients' lives that influence their views and preferences. For example, patients' families play a large role in shaping their experiences and beliefs and in supporting them,

particularly when they are sick. Ethicists in North America initially took an approach to patient autonomy that ignored the family, but more recent thought has recognized the importance of the family's supportive role.^{10,11}

Clinicians also should be sensitive to the needs of the family when a patient is sick.¹² Among these, according to a survey of family members in ICU waiting rooms, are the need to talk about negative feelings such as guilt and anger; to talk about the possibility of the patient's death; to be told what to expect before they go into the ICU for the first time; to visit at any time; to talk to the same nurse every day; to receive explanations that are understandable; to feel that there is hope; to have good food available in the hospital; to be assured that it is all right to leave the hospital for a while; and to feel accepted by the staff.¹³

Members of the ICU staff also should take note of the religious affiliation and cultural identity of their patients. However, they should not stereotype patients and presume to know what patients want based on their affiliation, but rather should be ready to inquire about each patient's views and should be respectful of diverse beliefs^{14,15} (Box 71.2).

COMMUNICATION WITH PATIENTS

From an ethical standpoint, communication is an important component of respect for patients; it is an indispensable ingredient for learning about patients' needs, values, and preferences. Many factors undermine communication with patients and with families in the ICU: insufficient time for staff members and patients to get to know one another and develop a trusting relationship, discomfort or fear of talking about illness and death, focus on the patient's physiologic function, and lack of a conducive setting for communication. However, taking time to talk to patients and families on a daily basis is a crucial element of respectful care.

Often, the ICU clinician must convey bad news. Recommendations for breaking bad news include the following¹⁶:

- Use a location that is comfortable, quiet, and private.
- Set aside adequate time for discussion.
- Check what the patient or family already knows.
- Give some warning that there will be unfortunate news.
- Let the patient's desire for information guide the discussion.
- Elicit and address the patient's reactions and concerns.
- Foster an appropriate level of hope.
- Be honest, caring, and empathic.

Communication with ventilated patients is particularly difficult. Clinicians should make every effort to use techniques designed to overcome communication barriers with ventilated patients.¹⁷

DECISION MAKING FOR COGNITIVELY IMPAIRED PATIENTS

Because many patients are, or may become, cognitively impaired, clinicians should frequently and repeatedly assess patients' capacity to understand their situation and make decisions. Judging the capacity of patients to make decisions can be difficult.^{18,19} Table 71.1 shows recommendations for assessing the relevant criteria: the ability to communicate a

Box 71.1 Elements of Good Ethical Practice in Medical Decisions in the Intensive Care Unit

- Careful assessment of the patient's condition
- Evaluation of the risks and benefits of therapeutic options
- Clear communication with the patient or proxy to inform about options and identify plan of care
- Identification and respect for a competent patient's or proxy's preferences
- Plan of care based on clinical assessment and mutually identified goals
- Tolerant of uncertainty when making decisions
- Tolerant of disagreement between parties
- Ongoing dialogue to resolve difficult situations

Box 71.2 Guiding Questions for Attending to Diverse Perspectives of Critically Ill Patients

Language

- What language do the patient and family prefer to use to discuss illness and disease? How openly do they wish to discuss diagnosis, prognosis, and death itself?

Religion

- What is their religious background and how avid is their religious affiliation?
- What do the patient and family think about the sanctity of life, and how do they conceive of death?
- Do they believe in miracles? Do they believe in an afterlife? Do they believe the body should be handled in a certain way after death?

Social, Political, and Historical Context

- Do any of the following factors affect the attitudes of the patient and family: the patient's status in the family, country of origin, or experiences such as poverty, refugee status, past discrimination, or lack of access to care?

Beliefs About Illness

- What do the patient and family believe are the causal agents in illness, and how do these relate to the dying process?

Decision-Making Style

- Who makes decisions about matters of importance in the family?
- Are the patient and family fatalistic about the course of events, or do they wish to take active control of events?

Social Support and Resources

- What resources, including community and religious leaders, family members, and language translators, are available to aid in the complex effort of interpreting cultural dimensions of a patient's illness?

Adapted from Koenig B, Gates-Williams J: Understanding cultural differences in caring for dying patients. *West J Med* 1995;163:244-249.

choice, to understand the relevant information, to appreciate the situation and its consequences, and to reason about treatment options. When patients are capable of decision making, they should be involved to the extent that they desire. Patients who have not prepared advance directives should be asked if they would like to prepare such a directive and should be asked to designate someone to hold durable power of attorney for them.

When such a conversation is not possible and no advance directive exists, clinicians should be aware that most states have laws that determine who has legal decision-making status for persons who have not assigned durable powers of attorney. When no family member or other surrogate is available to make decisions on behalf of a decisionally incapacitated patient who needs emergency treatment, the physician in charge should carefully document the pressing necessity for treatment even without consent.

COLLABORATIVE CARE

Care in the ICU is provided by a multidisciplinary team; good collaboration among its members is essential. Paying attention to the perspectives of all team members and respecting their skills and clinical judgment are ethically important and are associated with improved clinical outcomes.²⁰ Collaboration is valuable not only for individual patients' care but also to achieve optimal function of the unit as a whole.²¹

AVOIDING CONFLICTS IN THE INTENSIVE CARE UNIT

Because of the high stakes and emotional tension surrounding the care of critically ill patients, conflicts often arise among patients, family members, and staff. Strategies for avoiding conflict are worth pursuing because it often is difficult to resolve conflicts once they have arisen.

Conflict avoidance tactics should include the following: giving frequent information to families about patients' status, including realistic assessment of outcomes; acknowledging uncertainty regarding predictions, so that forecasts that do not come to pass are not an undue source of disappointment; coordinating the provision of information among ICU staff members, so that the patient and family receive consistent information about the patient's status and plans for care; and eliciting patient and family concerns.

JUSTICE-RELATED ISSUES

Because critical care is expensive and limited in supply, clinicians should deliver critical care services in a manner that distributes the benefits fairly. Much of the ethics literature has focused attention on making decisions that will allocate critical care resources justly. The issue is one of distributive justice; it arises most frequently when clinicians decide whether to admit or discharge patients from the ICU, and when they face triage decisions during periods in which resources are limited. Less obvious instances obtain whenever a clinician considers whether to use a marginally beneficial intervention.

Several dominant, contending theories of distributive justice provide plausible underpinnings for making such decisions. *Utilitarian* theory is based on the tenet that one should act in a manner that promotes the greatest happiness for the greatest number of people. An act is morally right if it brings about a greater amount of good than any other possible act under the circumstances. Such an assessment is *consequentialist* in that it is based on expected outcome. *Egalitarianism* is another prominent contender. This view holds that all humans are equal and should be treated equally in similar circumstances. *Social contract* theory holds that a just arrangement can be identified by asking rational persons to consider what scheme they would agree to if they had no idea whether or when it might be applied to themselves.

The ethical theory most commonly applied to decisions about admission, discharge, and triage is a utilitarian one. In other words, those patients who are expected to gain the most benefit from intensive care are considered the ones

Table 71.1 Legally Relevant Criteria for Decision-Making Capacity and Approaches to Assessment of the Patient

Criterion	Patient's Task	Physician's Assessment Approach	Questions for Clinical Assessment*	Comments
Communicate a choice	Clearly indicate preferred treatment option	Encourage patient to paraphrase disclosed information regarding medical condition and treatment	<p><i>Have you decided whether to follow your doctor's (or my) recommendations for treatment?</i></p> <p><i>Can you tell me what that decision is?</i></p> <p>If no decision, <i>What is making it hard for you to decide?</i></p>	Frequent reversals of choice due to psychiatric or neurologic conditions may indicate lack of capacity.
Understand the relevant information	Grasp fundamental meaning of information communicated by physician	Encourage patient to paraphrase disclosed information regarding medical condition and treatment	<p><i>Please tell me in your own words what your doctor (or I) told you about:</i></p> <ul style="list-style-type: none"> <i>the problem with your health now</i> <i>the recommended treatment</i> <i>the possible benefits and risks (or discomforts) of the treatment</i> <i>any alternative treatments and their risks and benefits</i> <i>the risks and benefits of no treatment</i> 	Information to be understood includes nature of patient's condition, nature and purpose of proposed treatment, possible benefits and risks of that treatment, and alternative approaches (including no treatment) and their benefits and risks.
Appreciate the situation and its consequences	Acknowledge medical condition and likely consequences of treatment options	Ask patient to describe views of medical condition, proposed treatment, and likely outcomes	<p><i>What do you believe is wrong with your health now?</i></p> <p><i>Do you believe that that you need some kind of treatment?</i></p> <p><i>What is the treatment likely to do for you?</i></p> <p><i>What makes you believe it will have that effect?</i></p> <p><i>What do you believe will happen if you are not treated?</i></p> <p><i>Why do you think your doctor has (or I have) recommended this treatment?</i></p>	<p>Courts have recognized that patients who do not acknowledge their illnesses (often referred to as "lack of insight") cannot make valid decisions about treatment.</p> <p>Delusions or pathologic levels of distortion or denial are the most common causes of impairment.</p>
Reason about treatment options	Engage in rational process of manipulating the relevant information	Ask patient to compare treatment options and consequences and to offer reasons for selection of option	<p><i>How did you decide to accept or reject the recommended treatment?</i></p> <p><i>What makes (chosen option) better than (rejected option)?</i></p>	This criterion focuses on the process by which a decision is reached, not the outcome of the patient's choice, because patients have the right to make "unreasonable" choices.

*Responses need not be verbal.

From Appelbaum PS: Assessment of patients' competence to consent to treatment. *N Engl J Med* 2007;357:1834-1840.

who should receive it. Accordingly, patients who are so severely ill that they are likely to die despite intervention and patients who are so minimally sick that intensive care will not add to the likelihood of their survival should not be admitted to ICU. Patients whose conditions are chronic and devastating, such as those in a permanent vegetative state, often are included among patients who should not receive intensive care for any acute life-threatening events, because their underlying illnesses are not amenable to improvement.

Of interest, Baker and Strosberg have argued that the assumption that triage is based on a utilitarian theory of justice is not correct.²² They point out that triage was developed by Larrey, surgeon general of Napoleon's army, as a strategy for systematically handling the wounded so that those who had to be attended to first got care without regard to rank, in keeping with the French Revolutionary commitment to liberty, equality, and fraternity. Baker and Strosberg suggest that an egalitarian form of triage is advantageous because the public is likely to voluntarily comply with it. Persons with normal "rational self-interest" would agree with it because it improves everyone's chances of survival. The chances of survival of the fatally wounded and the slightly wounded would not be significantly altered by deferred treatment. This optimal arrangement thus also is compatible with a social contract theory of justice.²³

Although triage strategies have relied on the probability of survival, some authors have argued that this is too crude an outcome measure to guide triage. Engelhardt and Rie have suggested that critical decisions to admit, continue care, or discharge patients should be based on a more complete formula that includes probability of successful outcome, quality of life, predicted length of life remaining, and cost of therapy.²⁴

ADMISSION CRITERIA

The Task Force on Guidelines of the Society of Critical Care Medicine (SCCM) and the American College of Critical Care Medicine (ACCM) have published recommendations for ICU admission and discharge.^{25,26} Each ICU should create a specific policy that explicitly articulates admission and discharge criteria and defines the services that it provides to the population served. Compliance with the policy should be monitored, and the policy should be revised as needed. Any decision to deny a patient admission should be made by clinicians who are familiar with expert opinion and relevant literature and should use established guidelines. Standardized criteria and guidelines facilitate fair rationing because they enhance the likelihood that patients will be treated similarly.

DISCHARGE CRITERIA

Discharge decisions should be guided by an assessment that less care is necessary and should take patient safety into account. Decisions to transfer a patient from the ICU to other hospital facilities should always be accompanied by good communication with the receiving team to avoid oversights and errors in care.²⁷ Straightforward indications would include, at one extreme, improvement in medical

condition that obviates the need for further intensive therapy or, at the other extreme, a decision to end intensive care because of impending death. The ethically challenging aspect of discharge criteria involves the question of discharge when a patient's probability of survival is expected to be only minimally improved by remaining in the ICU, but the probability is not zero.

TRIAGE

Triage decisions should be made explicitly and without bias. Ethnicity, race, gender, social status, sexual preference, and financial status should not be considered.²⁶ Factors that are appropriate to consider include probability of survival; likely functional outcome; age; chronic underlying conditions; marginal benefit to be gained; and preferences expressed by the patient or surrogate.²⁸ When the ICU is full, patients already in the ICU should not necessarily be given priority if someone else stands to benefit more from the care.²⁹ Like many ethically difficult decisions, triage decisions can be made more manageable by thinking proactively, every day, about the disposition of patients. For example, ICU physicians should regularly review the status of all patients in the unit to assess their degree of readiness for discharge in case the need for new admissions arises.²⁷ Application of this kind of strategy should involve cooperation with other patient care units in the hospital to arrange smooth transfer.

Even when policies are in place for fair triage through an admission approval process by a designated individual, attempts to circumvent admission rules by seeking permission from ICU clinicians or administrators who are on duty in the ICU are fairly common.³⁰ Therefore, policies should be designed to anticipate—and resist—such backdoor efforts.

In addition to decisions about admission, discharge, and triage, ICU physicians frequently must deal with the question of whether to offer or withhold treatments from patients with ultimately fatal injuries or illnesses. The ethical reasoning behind decisions to ration possibly beneficial interventions should be clear in the clinician's mind³¹; this issue is discussed more fully later in the section on termination of medical care.

Because expected benefit is a crucial factor in decision making, it is important for critical care physicians to understand the limits of prognostic guidelines for patients with life-threatening illnesses.³² Physicians should recognize the degree of uncertainty that surrounds mortality estimates. Although it is useful to consider a patient's expected outcome, and to use this prognosis to guide decisions, a false sense of certainty can lead to mistakes. Furthermore, communicating prognostic information with a false sense of certainty can lead to misunderstanding and subsequent distrust on the part of families. Prognostic scoring systems can serve as a useful baseline on which to build treatment recommendations, but firm thresholds should not be set. For a patient with a very uncertain prognosis, trying different treatments for short periods can avoid extended inappropriate treatments without denying care that has a minute chance of working. Medical decision making requires more than functional assessment and prediction. Scoring systems can provide an unbiased measure to help inform physicians'

decisions, but such measures should not be adopted as absolute guides.³²

DISPARITY IN USE AND OUTCOME OF INTENSIVE CARE

Critical care clinicians should be aware that a number of studies show a pattern of disparity in use of intensive care that is the result of forces outside the ICU itself. Patients of lower socioeconomic status have higher mortality rates.³³ Patients who lack health insurance are less likely to be admitted to hospitals; once hospitalized, however, they are more likely to be admitted to the ICU and more likely to die in the hospital.³⁴ Patients with private attending physicians are likely to stay longer in the ICU. Intensive care providers should try to prevent inequitable use of resources in the delivery of critical care services.

ETHICS CONSULTATION IN THE INTENSIVE CARE UNIT

In view of the many ethical dilemmas that arise in the ICU, proactive ethics consultation can be useful for reducing conflicts over treatment and for planning wise use of resources, as supported by good evidence.³⁵

THE ETHICS OF END-OF-LIFE CARE

The contemporary practice of critical care medicine includes consideration of the ethical issues surrounding end-of-life care including the definition of death, the ethical justification and legal precedent for withdrawing and withholding treatment, the concept of futility in administering treatments, and ethical issues in transitioning a patient to palliative care.

DEFINING DEATH

Given the emphasis on life and death decisions in intensive care, it is prudent for the critical care practitioners to be aware of the many philosophical questions surrounding the definition of death.³⁶ In any consideration of the definition of death, it is useful to recognize that death is more of a process than an instantaneous event and that the boundary between life and death is not perfectly sharp. The specification of any standard will require some arbitrary line drawing that has ethical implications.³⁶

Historically, death has been defined both legally and medically as the moment at which cardiac and respiratory function has irreversibly stopped. This definition of death has been termed the cardiopulmonary standard of death. The concept of using neurologic criteria to establish death did not emerge until the 1960s with the advent of mechanical ventilation, which allowed for circulation of oxygenated blood in the absence of brainstem function and called into question whether the cardiopulmonary criteria for determining death were sufficient for all patients. Advances in cadaveric organ transplantation also stimulated the question of whether separate neurologic criteria should be determined for death, which would allow the

procurement of viable organs from patients meeting a separate set of neurologic criteria.

In 1968, the Ad Hoc Committee of the Harvard Medical School to Examine the Definition of Brain Death determined that severely brain injured patients meeting certain diagnostic criteria could be declared dead prior to the cessation of cardiopulmonary function.³⁷ The use of neurologic criteria to determine death was subsequently accepted by some states in the United States. However, confusion remained with regard to what constituted “brain death”; specifically whether total brain nonfunction or brainstem nonfunction sufficiently fulfilled neurologic criteria for death. In response to the variability in state statutes regarding brain death, the President’s Commission for the Study of Ethical Problems in Medicine published a uniform statute for determining brain death, called the Uniform Determination of Death Act (UDDA). According to the UDDA, “an individual who has sustained either 1) irreversible cessation of circulatory and respiratory function or 2) irreversible cessation of all functions of the entire brain, including the brainstem is dead. A determination of death must be made in accordance with accepted medical standards.”³⁸

The ethical justification for using neurologic criteria to determine death relies on the presumption that in brain death, the body of the patient is no longer “a somatically integrated whole” and that in the absence of whole brain function, maintaining circulation, even with cardiorespiratory support, will stop imminently within a defined period of time.³⁹

Recently the use of brain death criteria has been questioned in the medical and bioethical community. Opponents of using brain death criteria cite the uncertainty in determining physiologic death by neurologic parameters. There is evidence that even in the setting of whole brain death many homeostatic functions can persist, including maintenance of body temperature, wound healing, the gestation of a fetus in a pregnant patient, and sexual maturation and growth in pediatric patients who fulfill the neurologic criteria for death.⁴⁰ In addition, cardiopulmonary death does not always occur in a timely fashion after brain death and in rare cases may take weeks or years to occur after brain death has been declared.⁴¹ Notably, arguments against neurologic standards of death do not preclude the ethical permissibility of withdrawing supportive care when the criteria of brain death have been met, but question whether these criteria alone constitute the death of the patient.

In response to concerns regarding brain death as a legitimate determinant of human death, the President’s Council on Bioethics revisited the philosophical and clinical dilemmas surrounding this issue in 2008.³⁹ The council’s ultimate conclusions were to support neurologic criteria of brain death with an alternative argument regarding defining death as the inability of the organism to function as “a somatically integrated whole.” Rather, “total brain failure” constitutes death as the patient, “is no longer able to carry out the fundamental work of a living organism. Such a patient has lost—and lost irreversibly—a fundamental openness to the surrounding environment as well as the capacity and drive to act on this environment on his or her own behalf . . . a living organism engages in self-sustaining,

need-driven activities critical to and constitutive of its commerce with the surrounding world. These activities are authentic signs of active ongoing life. When these signs are absent, and these activities have ceased, then a judgment that the organism as a whole has died can be made with confidence.”

Currently all 50 states and the District of Columbia have adopted the UDDA definition of brain death by statute or judicial decision. Two states, New Jersey and New York, have specific laws or regulations to address religious objections to neurologically based declarations of death.⁴² Similarly, over 90 countries use neurologic criteria to determine death in addition to traditional cardiopulmonary criteria.⁴³ The cultural variability in accepting neurologic criteria to determine brain death is exemplified in the organ transplant laws in China and Japan. In 2003, the Chinese Ministry of Public Health drafted a proposal to outline neurologic criteria that would define death in the absence of cardiopulmonary arrest. However, legislation approving the use of brain death criteria was not endorsed, lacking support from the public and health care professionals.⁴³ Prior to 2010, Japan’s Organ Transplant Law only recognized brain death when the patient had given prior written consent to be an organ donor and the family did not object to the donation. This law has since been revised to allow a determination of death based on neurologic criteria for the purposes of organ donation with family consent so long as the donor did not previously refuse organ donation. However, the revision still does not address whether neurologic criteria for death are sufficient in the absence of an anticipated organ donation.⁴⁴

WITHHOLDING AND WITHDRAWING LIFE-SUSTAINING TREATMENT

The first suggestion that physicians should withhold medical interventions from terminally ill patients probably dates to Hippocrates’s injunction to “refuse to treat those [patients] who are overmastered by their disease, realizing that in such cases medicine is powerless.”⁴⁵ In 1835, Jacob Bigelow urged members of the Massachusetts Medical Society to withhold “therapies”—such as cathartics and emetics—from hopelessly ill patients.⁴⁶ In 1848, John Warren, the surgeon who performed the first operation with ether anesthesia, urged that ether should be used “in mitigating the agonies of death.”⁴⁷ In 1958, Pope Pius XII, in response to questions about resuscitating patients and maintaining comatose patients on respirators, stated that physicians had no obligation to use such “extraordinary” means to forestall death.⁴⁸ The concept that the mere extension of life is not always in the best interest of the patient is perhaps even more apparent in current times, when advances in medical technology have led to the seemingly indefinite prolongation of the lives of the critically and terminally ill.⁴⁹

Many physicians find withdrawing life-sustaining treatment more difficult than withholding treatment. However, from a bioethical perspective, there is little distinction between withholding and withdrawing life-sustaining treatments.⁵⁰ Competent patients have the right to refuse medical care and can use whatever criteria they deem acceptable; it is their values that guide the choice.⁵¹ Every medical intervention, including artificial nutrition and hydration, may be terminated under some conditions.

The right to refuse medical interventions, including life-sustaining treatment, is supported by legal precedent (Table 71.2). Court decisions have sanctioned the withholding or withdrawal of respirators, chemotherapy, blood transfusions, hemodialysis, and major surgical operations. In its 1990 *Cruzan* decision, the U.S. Supreme Court recognized that competent patients have a constitutional right to refuse medical care.⁵²

Competent patients need not be terminally ill to exercise the right to refuse interventions; they have the right regardless of health status. Moreover, the right applies both to withholding proposed treatments and to discontinuing initiated treatments. This does not, however, imply that patients have a correlative right to demand treatment.^{53,54}

In theory, the right of patients to refuse medical therapy can be limited by state interests in the preservation of life, prevention of suicide, protection of third parties such as children, and preservation of the integrity of the medical profession.⁵⁴ In practice, these interests almost never override the rights of competent patients or of incapacitated patients who have left explicit advance directives.

ADVANCE CARE DIRECTIVES AND DURABLE POWERS OF ATTORNEY

Most patients at the end of life will have lost decision-making ability due to medical or cognitive incapacity. Advance care directives or appointed surrogate decision makers with instructions regarding the patient’s wishes serve as a critical resource in preserving patient autonomy in end-of-life care.

There are two types of advance care planning documents: living wills and proxy statements. *Living wills* or instructional directives are advisory documents specifying the patient’s preferences to specific care decisions. State-specific forms that people can fill in to draw up advance directives are available on the Internet.⁵⁵ Some advance directives, such as the Medical Directive, enumerate different scenarios and interventions for the patient to choose from.⁵⁶ Among these, some are for general use and others are designed for use by patients with a specific disease, such as cancer.⁵⁷ Less specific directives can be general statements of not wanting life-sustaining interventions or forms that describe the values that should guide specific terminal care decisions. Of importance, a person does not have to use a state-specific form because “a living will or health care power of attorney that does not strictly follow the statutory [state] form is also valid in most states” and the U.S. Supreme Court has ruled that a person has a constitutional right to refuse medical treatments.⁵⁸ Practitioners should be aware that living wills may have some legal limitations. For instance, in 25 states, a living will is not valid if a woman is pregnant; specific state statutes should be reviewed in caring for a pregnant patient.

The health care *proxy statement*, sometimes called a durable power of attorney for health care, specifies a person selected by the patient to make decisions. A combined directive includes both instructions and the designation of a proxy; the directive should clearly indicate whether the specified patient preferences or the proxy’s choice should take precedence if they conflict.⁵⁶

Many states permit clear and explicit verbal statements to be legally binding even if not written down.⁵⁸ However, such statements must be very explicit. In the *Wendland* case, a

Table 71.2 Major Legal Cases Regarding the Withholding or Withdrawing of Medical Interventions

Case and Citation	Year	State	Facts	Decision
<i>In re Quinlan</i> , 70 N.J. 10	1976	NJ	A 21-year-old woman in a persistent vegetative state was dependent on a respirator, artificial nutrition, and hydration.	The right to privacy includes a right to refuse medical care and extends to incompetent patients. Patient's guardian can withdraw her respirator. No need for judicial review in most cases.
<i>Superintendent of Belchertown v. Saikewicz</i> , 373 Mass. 728	1977	MA	A 67-year-old retarded man with a mental age of 2 years 8 months who had always lived in a state institution developed acute myelomonocytic leukemia. Did he have to receive chemotherapy?	All persons, including incompetent persons, have the right to refuse medical treatment. Using substituted judgment, the court determined that the patient would not want chemotherapy.
<i>In re Eichner (Brother Fox)</i> , 52 N.Y.2d 262	1981	NY	An 83-year-old priest was in a persistent vegetative state after a cardiac arrest. Before the event, he had publicly stated that he would not want to be respirator-dependent if he were vegetative.	Patients have the right to determine the course of their own medical care. Patient's wishes were known, even if not expressed in writing. Respirator should be withdrawn.
<i>In re Conroy</i> , 98 N.J. 321	1985	NJ	An 84-year-old bedridden, totally impaired woman with organic brain syndrome was being fed by a nasogastric tube. Her nephew requested removal of the tube.	Nasogastric tube feedings are medical interventions that can be withdrawn.
<i>Brophy v. New England Sinai Hospital</i> , 398 Mass. 417	1986	MA	A 49-year-old man in a persistent vegetative state after a ruptured aneurysm was maintained by gastric tube feedings. He had no written living will but had explicitly stated that he would never want to live on life support systems.	Common law and the constitutional right of privacy give a person the right to refuse medical treatment. The patient's wishes are clearly known from explicit conversations. The gastric tube can be withdrawn.
<i>Bouvia v. Superior Court</i> , 225 Cal. Rptr. 297	1986	CA	A 29-year-old mentally competent woman with cerebral palsy that left her almost completely immobile and totally unable to care for herself requested that a nasogastric tube to supplement her inadequate oral intake be withdrawn.	The patient has the "right to refuse any medical treatment even that which may save or prolong her life."
<i>In re Jobes</i> , 108 N.J. 394	1987	NJ	A 32-year-old woman in a permanent vegetative state was receiving J-tube feedings. Her husband and parents request withdrawal of the feedings. She left no clear written or verbal indication of her wishes.	Incompetent patients have the right to refuse medical care even if they have left no clear indication of their wishes. Using substituted judgment the family can exercise her right to withdraw the J-tube feedings.
<i>Cruzan v. Director of Missouri Department of Health</i> , 110 S. Ct. 2841	1990	U.S.	A 33-year-old woman in a persistent vegetative state was maintained by gastric tube nutrition and hydration. Her parents requested that these tube feedings be terminated.	Voting 8 to 1, the Supreme Court ruled that patients have a constitutional right to refuse medical care and that this applies to artificial nutrition and hydration. If there was no clear and convincing written or oral statement of the patient's wishes, states could regulate how families exercise the right.
<i>In re Helga Wanglie</i> , Fourth Judicial District PX-91-283, Minnesota (Hennepin County)	1991	MN	An 85-year-old woman in a persistent vegetative state was maintained on a respirator. After months, physicians suggested withdrawal of life-sustaining treatment because the patient was receiving no benefit. The family refused withdrawal.	The husband should represent the patient's interests, and his refusal to discontinue the respirator is binding.

Table 71.2 Major Legal Cases Regarding the Withholding or Withdrawing of Medical Interventions (Continued)

Case and Citation	Year	State	Facts	Decision
<i>Wendland v. Wendland</i> , 110 Cal. Rptr. 2d 412	2001	CA	A 42-year-old conscious man with severe cognitive impairments, hemiparesis, and limited communication who was not terminally ill required a feeding tube. The feeding tube fell out and needed to be replaced. After authorizing replacement of the feeding tube three times, wife refused replacement.	Patients have a right to refuse all medical treatments including life-sustaining treatments. This right can be exercised for mentally incompetent patients through advance care directives. For patients who are terminally ill, in a persistent vegetative state, or comatose who have not completed an advance care directive, proxies who have not been formally appointed can terminate interventions. However, for mentally incompetent but conscious patients, “clear and convincing” evidence of the patient’s wishes is needed before life-sustaining treatment can be stopped.
<i>In re guardianship of Schiavo</i> , No. 90–20–8GD–003, 2000 WL 34546715 (Fla. Cir. Ct. Feb. 11, 2000)	2005	FL	In February 1990, Terri Schiavo collapsed in her apartment. She was resuscitated but left in a persistent vegetative state not requiring a respirator but receiving artificial nutrition and hydration. Many attempts were made to rehabilitate her, including thalamic stimulation. In May 1998, her husband filed a motion to remove the nasogastric tube. This engendered conflict between her husband and her parents. Her parents claimed she would not want feedings ended and that her husband should not be the guardian. In 2000, a judge heard the case about her medical condition and wishes, and who should be her guardian. The judge ruled she was in a persistent vegetative state, her husband could make decisions for her, and she made oral declarations indicating she would not want to be kept alive in a persistent vegetative state. In 2003, Florida legislature passed “Terri’s Law” to give the governor power to intervene. Over 7 years, 14 appeals and 5 suits in Federal District Court led to removal and reinsertion of the feeding tube three times. In March 2005, the feeding tube was removed and Terri Schiavo died.	Terri Schiavo’s husband is the rightful guardian, there is oral evidence of patient’s wishes, and based on her wishes, her husband has the authority to make the decision to remove the feeding tube. Terri’s Law violates the Florida constitution.

42-year-old man suffered permanent brain damage and hemiparesis in a car accident.⁵⁹ The California Supreme Court ruled that when the patient is conscious and there is no advance care directive, there must be “clear and convincing” evidence of the patient’s view in order to permit withdrawal of a feeding tube.⁵⁹ “Clear and convincing” evidence requires prior comments to refer to the specific intervention in the specific circumstances of the patient, not a similar health state.

In 1984, California passed the first law recognizing the appointment of a designated proxy for health care decisions; by 2007, all 50 states and the District of Columbia had enacted statutes recognizing the durable power of attorney for health care decisions. There are some limitations. For instance, although most states permit proxies to terminate life-sustaining treatments, Alaska prohibits such decisions by proxies. In other states, orally appointed proxies are limited to a particular hospitalization or episode of illness.

Nevertheless, it appears that any properly filled-out, formal advance care document or durable power of attorney designation, whether or not it conforms to a state's specific document, is protected by the U.S. Constitution and must be honored.⁵²

Although advance directives can be helpful in guiding clinicians and family members, many patients have not prepared them. Despite polling data showing that approximately 80% of Americans endorse the use of advance directives, and passage in 1990 of the federal Patient Self-Determination Act (PSDA), which requires hospitals and other health care facilities to inform patients about their right to complete an advance care directive, less than 30% of the adult population in the United States has a formally prepared advance directive.⁶⁰ The use of advance care directives may be more prevalent in older adults. Silveira and colleagues used data from the Health and Retirement Study to survey the proxies of patients 60 years and older who had died between 2000 and 2006 and found that approximately 47% of these patients had advance directives.⁶¹

However, even when advance care directives have been prepared, they frequently are not in the patient's medical record, and the patient's physician may not be aware of the existence or content of the document.^{62,63} In addition, recent studies suggest that most advance directives are either proxy forms or standard living wills, and that few have any specific directions from the patient.⁶⁴ Finally, studies confirm that proxies and family members tend to be poorly informed about patients' wishes regarding end-of-life care and therefore are unlikely to make decisions as the patient would.^{65,66} Even if specific treatment courses are outlined, these directives may be outdated as preferences change with time or the patient's medical condition evolves. Ideally, advance directives should be revisited with the patient over time with family members or a physician with whom the patient has a long-term relationship.

For mentally incapacitated patients who appointed a surrogate decision maker but did not give specific indications of their wishes, or who never completed an advance care directive, four guiding decision criteria have been proposed: (1) futility of treatment, (2) the ordinary versus extraordinary care distinction, (3) substituted judgment, and (4) best interests.

FUTILE TREATMENTS

In the late 1980s and early 1990s, some argued that physicians could ethically terminate futile treatments.⁶⁷ However, citing medical futility as an ethical and legal justification for the withdrawal of life-sustaining treatments is not a clear-cut endeavor and has been criticized as inadvisable.^{68,69} The term *futility* carries both quantitative and qualitative meanings. There is little, if any, agreement among health care professionals as to what numeric threshold of probability should be considered an indication of futility. Medical futility also has a qualitative aspect that implies that the objective of the proposed treatment is not worthwhile.⁴² The qualitative definition of futility can be especially problematic when patients or their surrogate decision makers disagree with physicians about what constitutes a worthwhile outcome. In addition, a declaration by clinicians that a treatment is futile can marginalize patients and surrogates by effectively revoking their participation in treatment decisions. Thus, the

ambiguities in defining medical futility and the potential for alienation of patients and family members have led some bioethicists to propose that the term futility be replaced by the terms "medically inappropriate" or "surgically inappropriate" to more accurately describe an assessment that reflects a professional opinion rather than a summation of value.⁷⁰

Nonetheless, some states including Texas, Virginia, Maryland, and California have enacted so-called medical futility laws.⁷¹ These laws protect physicians from liability if they terminate life-sustaining treatments against family wishes. In Texas, if the medical team and the hospital ethics committee believe that interventions should be terminated, but the patient's family disagrees, the hospital is supposed to seek another institution willing to provide treatment.⁷¹ If, after 10 days, this fails, then the hospital and the physician may unilaterally withdraw treatments determined to be futile; however, the family may appeal to a state court. Early data suggest that the law increases futility consultations with the ethics committee, and that most families concur with withdrawal decision.⁷¹

Some hospitals have enacted "unilateral DNR" (do not resuscitate) policies to allow clinicians to provide a DNR order in cases in which consensus cannot be reached with families and there is medical opinion that resuscitation would not affect a patient's outcome. Because the ethical justification for unilateral DNR relies on the medical assessment that resuscitation efforts will not achieve the desired outcome (i.e., resuscitation is futile) the unilateral DNR remains a controversial policy. If a unilateral DNR is being considered by a physician, a second opinion by another physician and a hospital ethics committee consultation should be considered.⁴²

"Partial codes" and "slow codes" describe resuscitation efforts that are selective or foreshortened in the setting in which the medical team believes resuscitation efforts to be inappropriate and the patient's family or proxy will not agree to a recommended DNR order. Slow codes have been historically almost universally repudiated in the bioethics community. The American College of Physicians Ethics Manual cautions against slow codes as "deceptive, half-hearted resuscitation efforts."⁷² Ultimately slow and partial codes threaten the ethical principles of autonomy and beneficence. By neither attempting a full resuscitation nor invoking a unilateral DNR, the patient's or surrogate's decision is disregarded while administering a nonbeneficial treatment. However, more recently Lantos and Meadow have defended the practice of partial and slow codes when communication has been exhausted and intractable disagreements about cardiopulmonary resuscitation (CPR) persist.⁷³⁻⁷⁵ Supporters of the slow or partial code cite the symbolic value of CPR and delineate specific circumstances in which such a limited code would be ethically permissible such as when resuscitation will almost certainly be ineffective, the surrogate decision makers understand that death is inevitable, and the surrogates "cannot bring themselves to agree to a do-not-resuscitate order."⁷³ When compared to enforcing a unilateral DNR on a surrogate or family member, such a compromise may be a more compassionate option for those responsible for making a decision on DNR status. However, arguments supporting limited resuscitation are almost always focused exclusively on the welfare of the

surrogates, rather than the patient under the physician's care. Therefore, slow and partial codes should not be considered an acceptable practice in the care of critically ill patients.

ORDINARY/EXTRAORDINARY CARE

Following Pope Pius XII's and Roman Catholic teachings, some ethicists advocate a distinction between ordinary and extraordinary care: Ordinary care is considered to be mandatory, whereas extraordinary care may be withheld or withdrawn.⁴⁸ One commentator for the Catholic Hospital Association explained this distinction as follows:

Ordinary means of preserving life are all medicines, treatments, and operations, which offer a reasonable hope of benefit for the patient and which can be obtained and used without excessive expense, pain, or inconvenience. . . . *Extraordinary* means of preserving life mean all medicines, treatments, and operations, which cannot be obtained without excessive expense, pain, or other inconvenience, or which, if used, would not offer reasonable hope of benefit.⁷⁶

Many ethicists and courts have concluded that this distinction is too vague and has "too many conflicting meanings" to be helpful in guiding surrogate decision makers and physicians.^{53,54,77,78} As one lawyer noted, ordinary and extraordinary are "extremely fact-sensitive, relative terms. . . . What is ordinary for one patient under particular circumstances may be extraordinary for the same patient under different circumstances, or for a different patient under the same circumstances."⁷⁸ Thus, the ordinary versus extraordinary distinction should not be used to justify decisions about stopping treatment.⁵⁴

SUBSTITUTED JUDGMENT

The standard of substituted judgment is based on preserving the patient's right of self-determination in the absence of decisional capacity. Many courts advocate use of the substituted judgment criterion. Substituted judgment holds that the surrogate decision maker should try to imagine what the patient would do if the patient were competent.⁷⁷ That is, the surrogate should try to "ascertain the incompetent person's actual interests and preferences" and to make the decision that "would be made by the incompetent person, if that person were competent."⁷⁹

An emphasis on substituted judgment when counseling patients' surrogates in end-of-life care can sometimes help alleviate feelings of overwhelming responsibility and guilt if the decision is to proceed with withdrawal or withholding life-sustaining treatments. Similarly, in scenarios in which family members of the patient disagree on end-of-life decisions, focusing the conversation on what the patient would have wanted can, at times, help to resolve controversies.

In the absence of specific guidance from the patient, substituted judgment involves surmising what a patient would want, rather than a guaranteed fulfillment of the patient's wishes.^{54,80} Of note, patients who were surveyed varied regarding the extent to which they want families to strictly adhere to their personal wishes in making end-of-life decisions on their behalf.⁸¹

BEST INTERESTS

The best-interests criterion holds that treatment decisions should be made based on balancing benefits and risks and should select those treatments in which the benefits maximally outweigh the burdens of treatment.^{53,54} When the patient's wishes are truly unknown or cannot be inferred, the best-interests standard should take precedent.

For the best-interests standard to work, there must be some "objective, societally shared criteria" about what constitutes benefits and burdens.⁸² However, as is made clear by many court cases involving conflict between family members, or between family members and the medical team, no objective way of determining benefits and burdens, and how they should be balanced, has been recognized. One court suggested that burdens should be determined solely by levels of pain.⁵³ However, many people consider a permanent vegetative state to be a serious burden that they want to avoid, even if they do not feel pain. In the absence of an objective best-interests standard, families largely decide what constitutes a benefit or burden from their estimation of a patient's personal values.

As a matter of practice, physicians rely on family members to make decisions that they feel are best and only object if these decisions seem to demand treatments that the physician considers nonbeneficial. Without a perfect solution to the problems raised by proxy decision making, this approach may be the most reasonable one in difficult circumstances.

ETHICAL ISSUES IN TRANSITIONING PATIENTS TO PALLIATIVE CARE

Critical care clinicians have a particularly challenging responsibility when taking care of patients whose chances of survival are uncertain. Under such circumstances, clinicians need to understand how to use prediction tools such as the Acute Physiology and Chronic Health Evaluation (APACHE) tool or the Simplified Acute Physiology Score (SAPS) system, or SAPS II, to estimate the likelihood of survival. Awareness of the limited predictive ability of these tools is important for the ICU physician, who at the same time will use them to trigger decisions and interventions as part of a systematic approach to improving care.⁸³

Although prognosis is uncertain, clinicians are advised to attend to the dual goals of prolonging life and palliating symptoms. As a patient's prognosis becomes increasingly worse, consideration needs to be given to withholding or withdrawing life-sustaining treatments. Useful guidelines for withdrawing life support are shown in [Box 71.3](#).

Because decisions to limit life support should be shared with patients or their families, clinicians should be familiar with the important components of discussing these decisions. These components are summarized in [Box 71.4](#).

Critically ill patients require relief of symptoms regardless of their prognosis. Once a patient is thought to be dying, the focus of care increasingly shifts away from combined efforts to prolong life and palliate symptoms to more exclusive focus on palliative care. Critical care clinicians should aim to deliver high-quality palliative care ([Box 71.5](#)).

When the decision is made to withdraw treatment and focus on comfort care, necessary palliative interventions to

Box 71.3 Guiding Principles of Withdrawing Life Support

1. The goal of withdrawing life-sustaining treatment is to remove treatments that are no longer desired or do not provide comfort to the patient.
2. The withholding of life-sustaining treatments is morally and legally equivalent to their withdrawal.
3. Actions with the sole goal of hastening death are morally and legally problematic.
4. Any treatment can be withheld or withdrawn.
5. Withdrawal of life-sustaining treatment is a medical procedure.
6. *Corollary to principles 1 and 2:* When circumstances justify withholding a life-sustaining treatment, consideration should be given to withdrawing current life-sustaining treatment.

From Rubenfeld GD, Gordon SW: Principles and practice of withdrawing life-sustaining treatments in the ICU. In Curtis JR, Rubenfeld GD (eds): *Managing Death in the Intensive Care Unit*. New York, Oxford University Press, 2001.

relieve pain, alleviate air hunger, or assuage anxiety may cause the unintended effect of hastening death. The doctrine of double effect provides the ethical justification for providing care that may have harmful effects. This principle relies on the distinction between an intended versus a foreseen but unintended effect of treatment⁵⁰. There are a number of critics of this doctrine⁸⁴; some opponents of the doctrine of double effect deny that the distinction between intended and merely foreseen consequences has moral significance. Regardless of whether one relies on this doctrine, most clinicians and medical ethicists endorse the view that if the goals of care have shifted to alleviating symptoms of pain and discomfort, administering interventions to achieve these goals is ethically and legally permissible even if doing so results in hastening the patient's death.

PALLIATIVE SEDATION

Palliative sedation is a controversial practice in part due to the lack of a consistent definition. Administering sedatives to a dying patient in a titrated fashion for the purposes of specific symptom relief is an accepted practice in palliative care. However, the term palliative sedation has also been used to describe the practice of providing continuous sedation to the dying patient for the purposes of maintaining a sustained level of unconsciousness. In 2008, the American Medical Association (AMA) condoned the use of palliative sedation to unconsciousness to relieve intractable clinical symptoms unresponsive to "aggressive symptom-specific treatments." A palliative care team should be consulted to ensure that all other treatment options have been exhausted. Informed consent must be obtained from the patient or the patient's surrogate. Obtaining consent should include a thorough discussion addressing the degree and length of sedation with respect to achieving an intermittent or constant level of unconsciousness. The AMA Code of Ethics does not condone the use of palliative sedation to unconsciousness for the purposes of relieving existential suffering

Box 71.4 Components of a Discussion about End-of-Life Care in the Intensive Care Unit

Making Preparations before a Discussion about End-of-Life Care

Review previous knowledge about the patient and family.
Review previous knowledge about the patient's attitudes and reactions.
Review your knowledge of the disease—prognosis, treatment options.
Review your own personal feelings, attitudes, biases, and grief reactions.
Plan the location and setting: a quiet, private place.
Have advance discussion with the family about who will be present.

Holding a Discussion about End-of-Life Care in the Intensive Care Unit

Introduce everyone present.
If appropriate, set the tone in a nonthreatening way: "This is a discussion I have with all my patients."
Find out what the patient and family understand.
Find out how much the patient and family want to know.
Be aware that some patients do not want to discuss end-of-life care.
Discuss prognosis frankly in a way that is meaningful to the patient.
Do not discourage all hope.
Avoid temptation to give too much medical detail.
Make it clear that withholding life-sustaining treatment is not withholding caring.
Use repetition to show that you understand what the patient or family member is saying.
Acknowledge strong emotions and use reflection to encourage patients or families to talk about their emotions.
Tolerate silence.

Finishing a Discussion of End-of-Life Care in the Intensive Care Unit

Achieve common understanding of the disease and treatment issues.
Make a recommendation about treatment.
Ask if there are any questions.
Ensure that a basic follow-up plan is in place, and make sure the patient or appropriate family member knows how to reach you for questions.

Modified from Curtis JR, Patrick DL: How to discuss dying and death in the ICU. In Curtis JR, Rubenfeld GD (eds): *Managing Death in the Intensive Care Unit*. New York, Oxford University Press, 2001.

such as feelings of death anxiety, social isolation, or loss of control, citing that these symptoms are more appropriately and effectively addressed by alternative measures.⁸⁵ Other professional organizations including the American Academy of Hospice and Palliative Medicine (AAHPM) and the National Hospice and Palliative Care Organization (NHPCO) have released similar policy statements and recommendations and additionally recommend an interdisciplinary approach involving palliative care expertise.^{86,87} The NHPCO recognized the controversy surrounding palliative

Box 71.5 Quality Measures for Palliative and End-of-Life Care**Patient and Family-Centered Decision Making**

Assessment of the patient's decisional capacity
 Documentation of a surrogate decision maker within 24 hours
 Documentation of the presence and, if present, contents of advance directive
 Documentation of the goals of care
 Communication within team and with the patient and the family
 Documentation of timely physician communication with the family
 Documentation of timely interdisciplinary clinician-family conference

Continuity of Care

Transition of key information with transfer of the patient out of the intensive care unit (ICU)
 Policy of continuity of nursing service
 Emotional and practical support for patient and family
 Open visitation policy for family members
 Documentation that psychosocial support has been offered

Symptom Management and Comfort Care

Documentation of pain assessment and management
 Documentation of respiratory distress assessment and management
 Protocol for analgesia and sedation in terminal withdrawal or mechanical ventilation
 Appropriate medications available during withdrawal of mechanical ventilation

Spiritual Support for Patients and Family

Documentation that spiritual support was offered
 Emotional and organizational support for clinicians
 Opportunity to review experience of caring for dying patients by ICU clinicians

From Mularski RA, Curtis JR, Billings JA, et al: Proposed quality measures for palliative care in the critically ill: A consensus from the Robert Wood Johnson Foundation Critical Care Workgroup. *Crit Care Med* 2006;34:S404-S411.

sedation to unconsciousness for relief of existential suffering and the panel was unable to reach an agreement on recommendations regarding this practice.⁸⁶

EUTHANASIA AND PHYSICIAN-ASSISTED SUICIDE

Administering treatments to hasten death as a way to relieve pain and discomfort falls into the realm of euthanasia and physician-assisted suicide. The term *euthanasia* requires clarification. So-called passive euthanasia is the withdrawal or withholding of life-sustaining medical interventions and is widely accepted as both ethical and legal. "Indirect euthanasia"—such as increasing narcotic dosage to ease a patient's pain, even if this has the consequence of hastening the patient's death—also is a misnomer; it generally has been deemed both ethical and legal for more than 100 years.⁸⁸ Almost all commentators agree that involuntary and non-voluntary active euthanasia are unethical because they end the life of a patient without consent. Consequently, the

focus of debate is on physician-assisted suicide and voluntary, active euthanasia. To avoid confusion, use of the term *euthanasia* should be restricted to voluntary, active euthanasia.

Proponents typically cite four reasons to justify physician-assisted suicide or euthanasia.^{88,89} First, they claim that euthanasia ensures patients' autonomy. How a person dies is essential to that person's values. Therefore, to respect patients' autonomy, it is mandatory to respect their wishes regarding the manner and timing of their death, through euthanasia and physician-assisted suicide.^{90,91} Second, for some patients, dying causes pain and suffering. A main purpose of euthanasia or physician-assisted suicide is a comfortable, quick death. Hence, euthanasia or physician-assisted suicide furthers beneficence, which is one of the major principles of medical ethics.^{90,91} Third, euthanasia and physician-assisted suicide are morally equivalent to terminating life-sustaining treatments. The goal is the same: a peaceful, painless death. Furthermore, there is no difference between an act of omission and an act of commission.⁹¹ Finally, the potential adverse consequences of legalization are speculative.

Opponents of euthanasia and physician-assisted suicide offer four parallel but opposite arguments. First, autonomy does not justify euthanasia or physician-assisted suicide.⁹²⁻⁹⁴ Autonomy does not mean a person should be permitted to do anything he or she wishes. Both Kant^{94a} and Mill^{94b} thought that a person's autonomy could be limited to prevent voluntary dueling or slavery. Similarly, one could argue that because euthanasia and physician-assisted suicide are aimed at ending autonomy, they can be limited without infringing autonomy. Second, many terminally ill patients receive inadequate treatment for pain, fatigue, and depression. With proper treatment, few people would experience pain and suffering of a level sufficient to justify euthanasia or physician-assisted suicide. Third, acts of omission and acts of commission are not equivalent. The ethical validity of an act does not depend solely on its final result but also stems from the intention of the person performing it. When physicians stop a medical intervention, they are stopping unwanted bodily intrusion, not trying to end a person's life; euthanasia and physician-assisted suicide do aim to end a person's life.^{38,92-94} Finally, permitting euthanasia and physician-assisted suicide would have a variety of well-documented adverse consequences. These effects include disruption of the doctor-patient relationship, intrusion of the courts, and possibly extension of euthanasia to children, mentally incapacitated patients, and others.⁹⁴

Although the U.S. Supreme Court has upheld the right of patients to reject medical treatment, the Court ruled unanimously in 1997 that there is no constitutional right to euthanasia or physician-assisted suicide.⁹⁵ Of importance, the U.S. Supreme Court did permit individual states to legalize these interventions. Oregon and Washington state have enacted legislation permitting physician-assisted suicide.^{96,97} The Supreme Court of the state of Montana has ruled that prohibition of physician-assisted suicide is against the state's constitution.⁹⁸

The Netherlands and Belgium have legalized both euthanasia and physician-assisted suicide. Their legislation included the following safeguards: The patient must have unbearable pain and suffering that cannot be medically

relieved; the patient must be competent and must repeatedly request to have his or her life ended; and the physician must consult a second physician.⁹⁹ In 2008, Luxembourg legalized euthanasia for patients with a “grave and incurable” condition. The physician must first consult a colleague and the patient must have repeatedly asked for the intervention.¹⁰⁰

For a brief period the Northern Territory of Australia had legalized euthanasia, but this was rescinded by the national legislature.¹⁰¹ In Switzerland assisted suicide is legal and the assistance need not be provided by a physician.¹⁰²

After receiving a request for euthanasia or physician-assisted suicide, health care providers should carefully clarify the request with empathetic, open-ended questions to help elucidate the underlying cause. Health care providers must reassure the patient of their continued care and commitment. The patient should be educated about alternative, less controversial options, such as symptom management and withdrawal of any unwanted treatments. Physicians also should discuss the realities of euthanasia and physician-assisted suicide, because the patient may have misconceptions about their effectiveness and the legal implications of the choice.

In addition, the physician should reevaluate the patient’s condition—not just for physical and psychological symptoms but also for lack of social support and spiritual fulfillment and need for care, which are strongly associated with interest in euthanasia and physician-assisted suicide. The physician should reassess whether additional interventions are required, including psychiatric evaluation, palliative care consultations, availability of skilled or unskilled home health care, and pastoral services. Obviously, the patient and family should be reassured that the physician will not abandon them and will provide care and attend to the patient’s symptoms and needs.

RESEARCH IN CRITICALLY ILL PATIENTS

Research involving critically ill patients in the ICU presents special ethical challenges. Chief among these challenges is the recognition of the distinction between clinical care and research. Although clinical medicine aims at providing optimal medical care for individual patients, clinical research lies outside the context of the doctor-patient relationship. It is designed to answer a scientific question, with the aim of promoting the medical good of future patients. Research abuses occur when interest in advancing science is allowed to outweigh concern for protection of human research participants. Adherence to ethical principles for research serves to minimize the possibility of such abuses and enhances the public trust in the research endeavor.

HISTORY AND FUNDAMENTALS OF HUMAN RESEARCH ETHICS

Among the first documented experiments with human subjects were vaccination trials in the 1700s. In these early trials, many physicians used themselves or their family members as test subjects. Even these early practices were not without some formulations of research ethics. In 1865, the French physiologist Claude Bernard wrote that the first principle of medical morality “consists in never performing on man an

experiment which might be harmful to him to any extent, even though the result might be highly advantageous to science.”¹⁰³ Louis Pasteur is reported to have “agonized” over performing a previously untried intervention in humans, even though he was confident of the results obtained through animal trials. He finally did so only when he was convinced that the death of the first test subject “appeared inevitable.”¹⁰⁴

The rise of the experimental method in medicine in the late nineteenth century led to an acceleration of the progress of medicine. Clinical trials became large-scale endeavors, but many trials targeted vulnerable groups of persons who could not protect their own interests, such as orphans, the mentally ill, and prisoners. During this era, no formal codes of research ethics existed to guide scientists in their experiments.

In the twentieth century, the medical experiments conducted by German physicians on concentration camp prisoners during World War II ushered in a new era of research ethics. After the war, 23 Nazi doctors and scientists were put on trial at Nuremberg for the torture and murder of concentration camp inmates who were used as research subjects. Most were convicted and sentenced to death or prison terms ranging from 10 years to life.¹⁰⁵

The Nuremberg judges were convinced that the Hippocratic Oath alone could not serve as an adequate foundation for ethical research. Accordingly, their principles for research, which became known as the Nuremberg Code, were meant to protect subject welfare as well as basic human rights.^{106,107} They formed the basis of the research ethics codes that are used internationally today.

The Nuremberg Code’s first principle was stated as a basic human right: “The voluntary consent of the human subject is absolutely essential.” Another basic right of research subjects was the right to withdraw from an experiment at any time. The other eight principles aimed to protect the welfare of human subjects by insisting, for example, that only qualified scientists conduct the research, that physical and mental suffering are avoided, and that risks are balanced against the importance of the scientific problem to be solved.

In the United States, the fundamental ethical guidelines for medical research were set out in 1974 by the National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research, which was established by Congress after a series of ethical scandals in the 1960s and 1970s. In its *Belmont Report*, the Commission outlined three basic ethical principles for the conduct of medical research: *respect for persons*; *beneficence*; and *justice*.¹⁰⁸ (Table 71.3).

Respect for Persons. *Respect for persons requires that people should be treated as autonomous agents and that those with diminished capacity, such as children or the mentally ill, are entitled to special protection. To respect autonomy is to give weight to a person’s considered opinions and choices. To show lack of respect for autonomy is to repudiate a person’s considered judgments, to deny the person the freedom to act on those considered judgments, or to withhold information necessary to make a considered judgment, when there are no compelling reasons to do so. Respect for persons is manifested in the informed consent process, in which potential subjects are provided with information about the experiment and then are allowed to decide whether to participate.*

Beneficence/Nonmaleficence. *Treating people in an ethical manner means not only respecting their decisions but also making*

Table 71.3 Principles and Derived Requirements for Ethical Research

Respect for Persons	Beneficence; Nonmaleficence	Justice
Persons should be treated as autonomous agents	Minimize possible harms	Fairness in distribution of risks and potential benefits of research to all groups
Persons with diminished autonomy need protection	Maximize societal and potential individual benefits	Fairness in selection of subjects
Informed Consent	Social Value	Fair Subject Selection
Disclosure of information	Research will lead to knowledge that will improve societal health	Vulnerable subjects are not targeted for enrollment because of their compromised position
Understanding of information	Scientific Validity	Aims of research dictate subject selection
Voluntariness of decisions	Research will produce reliable and valid data	When possible, less burdened groups of persons should bear the risks of research
Surrogate consent for vulnerable persons	Selected subjects are likely to be recipients of future benefits	
	Favorable Risk-Benefit Ratio	
	Risks are identified	
	Risks are minimized	
	Benefits are maximized	
	Risks are reasonable when compared to potential benefits to subject and society	
	Independent Review	
	Persons free from controlling influences review research to enhance implementation of ethical requirements and enhance subject protection	

efforts to secure their well-being. Such treatment falls under the principle of beneficence, which obliges physician-researchers to (1) do no harm and (2) maximize possible benefits and minimize possible harms. Beneficence requires that investigators and members of institutional review boards (IRBs) analyze the risks and benefits to the subjects, making sure that anticipated risks are proportional to the potential benefits. Risk should be minimized as much as possible.

Justice. Justice requires that the benefits and burdens of research be distributed equitably. Subjects should not be chosen simply because they are available and easy to manipulate. In addition, subjects who are likely to benefit from a study should not be excluded. Finally, whenever research supported by public funds leads to the development of therapeutic devices and procedures, these should be available not only to the wealthy but to all society; and such research should not unduly involve groups who are unlikely to benefit from the research.

The U.S. federal regulations and most international regulations governing research with human beings are largely based on these principles.

PUTTING PRINCIPLES INTO PRACTICE: APPLICATIONS

Although ethics codes and regulations exist to ensure the ethical conduct of research, what is needed is a systematic and coherent framework for evaluating the ethics of human subject research that incorporates all relevant ethical considerations. Stemming from the principles of research ethics, several *requirements* have been proposed to ensure the ethical conduct of research set out in the Belmont Report (see Table 71.3).

SCIENTIFIC VALIDITY

Clinical trials must be designed to answer valuable scientific questions with the necessary methodologic rigor to validly claim any scientific conclusions. The large number of therapeutic interventions required in the care of the critically ill creates special challenges in the conduct of clinical trials in the ICU.

The ideal clinical trial establishes whether therapeutic interventions work and determines the overall benefits and risks of each alternative. This is achieved by limiting the effects of chance, bias, and confounding. The need for scientific rigor also must be balanced against other requirements of clinical trials, such as protection of subjects' rights and welfare as well as minimizing the cost and the number of subjects necessary for enrollment to achieve significant results.¹⁰⁹

An important ethical construct in clinical trials is that of clinical *equipoise*.¹¹⁰ This concept refers to the existence of an "honest, professional disagreement among expert clinicians" concerning the relative benefits and harms of the interventions being tested.¹¹⁰ The presence of clinical equipoise serves two important goals.¹¹¹ It assures a physician that random selection of the intervention that a research participant will receive is ethically permissible, as neither of the interventions in the study groups dominates the other in terms of perceived safety and efficacy. Accordingly, the welfare of research subjects is not knowingly sacrificed for the interests of future patients. The other goal ensures that the results of the research will disturb clinical equipoise and hence yield reliable, generalizable information regarding the standard of care. The randomized controlled trial (RCT) is a formal method of resolving uncertainty about scientific knowledge, although well-conducted observational cohort and case-control studies also can provide

valuable information to disturb equipoise and might lead to better human subject protections.^{112,113} Several research methods have raised specific ethical issues in critical care research and deserve special mention. Some examples follow.

Placebo Controls

Clinical research involving placebo controls in circumstances in which an established therapeutic alternative is not available is not ethically problematic. In this situation, an experimental intervention (e.g., a new drug) is compared with a placebo and both may be superimposed on the current standard of care for the enrolled research participants. Placebo controls have been used in trials of critical care treatments for a wide range of conditions, including asthma and pulmonary hypertension.^{114,115}

In contrast, the use of a placebo control group, when a proven effective treatment exists for the medical condition, does raise ethical issues. Critics of placebo-controlled trials contend that when effective treatments exist, placing patients in a placebo group is not only unethical but also unwise. They argue that no scientific or clinical value derives from determining whether an investigational drug is better than an inert placebo; instead, they say, an experimental treatment should be compared with a standard treatment, to demonstrate which is better.^{116,117}

Advocates of placebo-controlled studies argue that such studies are not only ethical but indeed necessary under many circumstances.¹¹⁸⁻¹²⁰ For example, an experimental therapy may have fewer side effects or may be more effective for particular subgroups of patients, but these effects might not be recognized in active-control trials. Moreover, demonstrating that a new treatment is equivalent to an existing treatment may not prove that the new treatment is effective; both treatments could be ineffective. And comparing an experimental treatment with an existing treatment would require many more patients in each arm of the study than are necessary for a placebo-controlled trial.

To be sure, a placebo-controlled trial would be unethical when life-saving—or at least life-prolonging—treatment is available, and if patients assigned to receive placebo would be substantially more likely to suffer serious harm than those assigned to receive the investigational agent. Such trials involving diseases that are less serious, however, may be ethically appropriate if compelling methodologic reasons exist to conduct a placebo-controlled trial, and if the known harm associated with forgoing standard of care treatment in the placebo group would be mild to moderate in degree and reversible.

Choice of Control in Clinical Trials Comparing a New Intervention with the Current Standard of Care

If a new intervention is going to be compared to contemporary standard practice the control must be representative of current practices both to permit a useful comparison and to protect the welfare of research participants, as the inclusion of such a control group allows a trial to be stopped early if the tested intervention has a mortality rate or survival rate that is significantly higher than standard practices.¹²¹

The difficulty in control group selection is made more manifest when current practices of critical care practitioners

are variable. Accordingly, the choice of control group may involve a set protocol that is designated as the standard of care, and there are constraints on all treatment in both the experimental and standard-of-care control groups. Such constraints serve to improve the signal-to-noise ratio and increase the likelihood of finding difference between the tested interventions.¹²² However, the cost of using such control groups that enhance scientific validity is reduced generalizability and a potential to increase the risk of harm to enrolled research subjects.^{109,122,123}

In recognition of this concern, several critical care trials have used so-called “usual care” control groups whereby the control group represents the broad range of current practices and care is individualized for each patient. Several important critical care studies,¹²⁴⁻¹²⁸ including those involving mechanical ventilation,¹²⁹⁻¹³¹ have proved to be extremely informative.¹³² Surveys and observational studies of clinicians’ practice patterns would help ensure that such control groups reflect usual care. An international trial evaluating two target ranges for glycemic control in ICU patients took such an approach.¹³³

INFORMED CONSENT

Informed consent is the ethical prerequisite for all clinical trials involving human beings. The informed consent process respects subjects’ autonomy and ensures that they are not to be used merely as a means to another’s end.¹³⁴ It also provides research subjects a mechanism to protect themselves.^{135,136} Practices regarding obtaining informed consent from critically ill patients differ among researchers; for example, there is a difference in the extent to which participants consent personally rather than having a surrogate do so.¹³⁷

Valid informed consent consists of three major elements: disclosure of information, subject competence to make a decision, and voluntariness of the decision.¹³⁸

Disclosure of Information

The basic elements of information that should be communicated to potential subjects and their surrogates include a full description of any reasonably foreseeable risks or discomforts a subject may experience, and full disclosure of other procedures or courses of treatment that are available.^{139,140} (Box 71.6). Some of these elements are absent in many informed consent forms, including those used in critical care clinical trials.^{141,142} Recommendations for writing informed consent forms for critical care studies have been published.¹⁴³

Decision-Making Capacity

In order to give valid informed consent to research, potential research participants must be able to understand the information given to them, to understand or appreciate their situation and its consequences, to be able to rationally consider information in light of their underlying values, and to be able to commit to a decision.

Critical care investigators face a difficult task of recruiting research subjects who may have diminished capacity to give valid informed consent. Patients with acute illnesses often have limitations in their decision-making capabilities due to a number of factors, including the presence of delirium, their underlying illness, or the use of sedatives and

Box 71.6 Required Basic Elements of Informed Consent for Research in Critically Ill Patients

Element 1: Description of Research

- a. Purpose of the research
- b. A statement that the study involves research
- c. Expected duration of the subject's participation
- d. Description of the procedures to be followed and identification of any procedures that are experimental

Element 2: Risk

Description of any reasonably foreseeable risks or discomforts to the subject

Element 3: Benefits

Description of benefits that might reasonably be expected from the research:

- a. To the subject
- b. To others

Element 4: Alternatives

Disclosure of alternative procedures or courses of treatment, if any, that might be advantageous to the subject

Element 5: Confidentiality

Assurance of confidentiality

Element 6: Risk Management

For research involving more than minimal risk, if research injury occurs:

- a. An explanation as to whether any compensation is available
- b. An explanation as to whether any medical treatments are available

Element 7: Contact Information

- a. An explanation of whom to contact for answers to questions about the research
- b. An explanation of whom to contact for questions about the research subjects' rights
- c. An explanation of whom to contact in the event of a research-related injury

Element 8: Voluntariness

- a. Voluntariness of participation
- b. Assurance that subject may discontinue participation without penalty or loss of benefits to which the subject is otherwise entitled

analgesics.¹⁴⁴⁻¹⁴⁶ Understanding is less complete in severely ill patients than in healthier patients.¹⁴⁷ Research participants enrolled in clinical trials often have limited understanding of the research to which they have consented.^{148,149} Many potential participants may not understand certain concepts of randomization, the notion of a placebo design, research risks, and the distinction between research and clinical care. Understanding is less complete in severely ill patients than in healthier patients.¹⁴⁷ Investigators should make special efforts to ensure that potential research participants understand these general concepts and their implications for the specific study participants may be consenting to.

Investigators also should keep in mind that written descriptions of the research may not be effective in conveying information—particularly if the written material is so long and technical that potential research participants do not read it fully. Information given verbally can enhance understanding by giving research participants the opportunity to engage in a dialogue with the investigator. The opportunity for such a dialogue for patients receiving ventilatory support is difficult, and hence, the feasibility of enrolling such individuals with their own informed consent might be ethically problematic. One approach to such potential research participants who have some degree of decisional capacity is to obtain their assent in conjunction with proxy consent.¹³⁷

Regarding the distinction between research and clinical care, patients and families have a strong tendency to inaccurately attribute therapeutic intent to the research.¹⁵⁰ Physician-investigators should explicitly refute such a “therapeutic misconception” and should dispel any notion that a clinical trial is designed to or will provide patients with direct benefits, or that the research substitutes for clinical care.^{108,151}

Finally, the research community often assumes that research participants derive benefits solely from participating in a research study—even if they are receiving inert placebo—because of the extra monitoring and superior care associated with academic “centers of excellence.” Such an “inclusion benefit,” however, has not been proved.^{152,153}

Voluntariness

Valid informed consent requires that patients' decisions to enroll in clinical trials are free from coercion—including a fear, justified or not, that they may be harmed in some way if they do not enroll in the clinical trial.¹⁰⁸ The institutional setting of the research may be a source of subtle or covert coercion. Critically ill patients often lack decisional capacity. Patients may feel they have little choice but to participate in research when “their doctor” asks them to do so—particularly if their treating physician occupies the dual role of clinician-investigator. Accordingly, someone other than the treating physician should obtain informed consent from patients.^{154,155}

Another factor that may affect voluntariness is the presence of undue influence, which occurs when offers to induce enrollment, such as financial payments or free medical care, are of such magnitude that they influence subjects' decisions.¹⁵⁶

PROXY CONSENT

Ethically acceptable research may proceed with critically ill patients who are—or are at risk of becoming—decisionally impaired, if the investigators receive appropriate proxy consent.^{157,158} U.S. and European standards require proxy or surrogate decision makers to be legally authorized to provide such consent. In the United States, the legal representative for the patient is determined by the applicable state laws.

If possible, surrogate decision makers should follow the “substituted judgment” standard: They should make a good-faith judgment of what the subjects would have decided if capable of making a decision themselves. As discussed earlier, however, surrogates often do not know patients' previous preferences.^{159,160} Therefore, they also should consider what would be in the best interests of the patient.

Investigators should appreciate that family members of critically ill patients have high levels of anxiety and psychological distress that might impair their ability to give adequate informed consent for research participation for incapacitated patients.^{161,162}

If research participants who were entered into a trial through proxy consent regain decisional capacity during the trial, investigators should obtain their informed consent for continuing their participation.¹⁶³ Such retrospective consent should be sought even when the research procedures have been completed, because research participants have a right to know that they have participated in a trial and that further data may be collected. Whether participants should be given the right to withdraw the data obtained from them when they were unconscious is an unsettled issue. This is a sound proposal, ethically speaking, but from a methodologic standpoint it is arguable because it could ruin the comparability of study groups.

WAIVER OF INFORMED CONSENT

In some circumstances, the informed consent requirement can be waived—but only when an IRB finds that all of the following conditions are met:¹³⁹

- The research involves no more than minimal risk to the research participants.
- The waiver or alteration of informed consent requirements will not adversely affect the rights and welfare of the research participants.
- The research could not practicably be carried out without the waiver or alteration.
- Whenever appropriate, the participants will be provided with additional pertinent information after participation.

Under U.S. regulations, research may be characterized as minimal risk if “the probability and magnitude of harms or discomforts anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests.”¹⁶⁴ In other words, the types of minimal risks that are considered socially acceptable, such as in driving to work or crossing a street, or those encountered in routine physical or psychological evaluations, are acceptable in research.

An IRB can grant a waiver of informed consent for research assessing interventions in medical conditions that frequently occur in emergency situations such as cardiac arrest, stroke, shock, severe arrhythmias, and life-threatening traumatic injury. Patients with these conditions cannot give consent, and the narrow time window in which treatment must be given often does not afford sufficient time to obtain consent from a legal representative. A trial assessing the safety and efficacy of an infusion of low-dose steroid in severe septic shock provides a good example.¹⁶⁵

Various countries and regions have differing regulations governing such research. In 1996, the U.S. government specified several mechanisms under which research involving incapacitated research participants in emergency situations can be allowed without informed consent of a legally authorized representative.¹⁶⁶ But these procedures have been criticized as unnecessarily complicated and burdensome.¹⁶⁷⁻¹⁶⁹

A European Directive regarding clinical research involving drugs contains no provisions for waiver of informed

consent for research in emergencies. Some European countries, however, provide for possible waivers in their own regulations.¹⁷⁰

Australia’s National Statement on Ethical Conduct in Research Involving Humans allows an ethics committee to approve research without prior consent provided that (1) inclusion in the research is not contrary to the interest of the patient; (2) the research is intended to be therapeutic, and the research intervention poses no more risk than that inherent in the patient’s condition and alternative methods of treatment; (3) the research is based on valid scientific hypotheses that support a reasonable possibility of benefit over standard care; and (4) as soon as reasonably possible, the patient or the patient’s relatives or legal representatives, or both, will be informed of the patient’s inclusion in the research and of the option to withdraw from the research without any reduction in quality of care.¹⁷¹

Regulations in Canada stipulate that research in the emergency setting may proceed under the following conditions: if a serious threat to the prospective subject requires immediate intervention,¹⁷² if no standard efficacious care exists or the research offers a real possibility of direct benefit to the subject in comparison with standard care, or if the risk of harm is not greater than that involved in standard efficacious care or is clearly justified by direct benefit to the subject.

ANALYSIS OF RISKS AND BENEFITS

The U.S. federal regulations require that risks to research participants are reasonable in relation to anticipated benefits, if any, to the research participants, and the importance of the knowledge that may reasonably be expected to result. This assessment of the potential risks involves three steps.¹⁵⁷ First, the risks and discomforts of the trial must be identified; these factors include not only the physical risks but also psychological, economic, and social risks, including those that might emanate from breaches of confidentiality. Second, the risks must be minimized by changing the study design if possible—for example, excluding research participants who are at substantially higher risk, replacing invasive procedures with less risky procedures, or providing enhanced safety monitoring, for example, additional blood studies to monitor for safety. Finally, the risks must be reasonable when weighed against potential benefits to the research participants and to society. In weighing risks and benefits, some ethicists have found it useful to use a component analysis, which distinguishes between procedures with potential for benefiting research participants and procedures that merely answer a scientific question, without offering a potential direct benefit to research participants.^{158,173}

Within a component analysis, a study should be acceptable only if the risk of each component of the research—that is, each procedure the researchers will carry out—is justified separately by the corresponding potential benefit. Hence, a procedure that has no potential to benefit the subject but is designed solely to answer a research question is justified only if the risks of that procedure are reasonable in relation to its potential to generate scientific knowledge—a so-called risk-knowledge calculus. Procedures that may directly benefit the research participant are justified only if the risks are reasonable in relation to the potential benefit

and the potential scientific knowledge meets an additional standard of equipoise: There must be genuine uncertainty about whether the balance of risks and potential benefits of the experimental intervention are superior to those of accepted practice.

A component analysis is intended to avoid what has been termed the “fallacy of the package deal” in which the potential benefits of one intervention are considered to justify the risks of a another intervention in the study.¹⁷⁴

Justifying risks by the separate components of the study does not imply that there is no upper limit to acceptable risk.¹⁷⁵ However, what the risk threshold should be is debatable. When investigational procedures do not offer a prospect of direct benefit to the patient, commentators have argued that the risk should be capped at the level of minimal risk.^{176,177} This position reflects the concern that vulnerable subjects should not be put at undue risk for the sake of society and that such research is exploitative. However, advocating such a risk ceiling would seriously impair important research. Instead of restricting such research, a desirable alternative might be to institute a safeguard for this risk level, such as the “necessity requirement.” Such a safeguard would provide that decisionally impaired research participants can be enrolled in research only when their participation is scientifically necessary—for example, when the desired information cannot be obtained by enrolling adults who can consent. To provide supplemental protection, some guidelines reinforce the necessity requirement with a “subject condition” requirement, under which the research must involve a condition from which the subject suffers.

CORE SAFEGUARDS FOR VULNERABLE SUBJECTS

The U.S. federal regulations state that when some or all of the research participants are likely to be vulnerable because of intrinsic factors, such as lack of capacity to make decisions, or because of situations that threaten voluntary choice, such as coercive settings or undue inducements, additional safeguards must be included in the study to protect the rights and welfare of these individuals.

Although the U.S. regulations are silent regarding specific safeguards to provide additional protections to adults unable to provide consent, other guidelines have proposed examples of specific safeguards.¹⁷⁸ These safeguards include (1) assessment of potential research participants’ decision-making capacity; (2) respect for potential participants’ assent and dissent; (3) “necessity” requirement to ensure that research cannot be performed without enrolling incapacitated adults; (4) “subject-condition” requirement, whereby the research involves a condition from which the subject suffers; (5) an independent participation monitor to monitor participants’ involvement as they progress through the study protocol; and (6) an independent and (7) sufficient evidence of subjects’ prior preferences and interests.

Additional protections for vulnerable people and groups should be based on the level of risk of the procedures that will be involved.^{172,175,179} For example, for research involving potential direct benefits that pose more than minimal risk, additional protections for vulnerable subjects could include designating independent monitors to witness the informed consent process or to determine when it might be appropriate to withdraw the subject from the study.^{177,180}

MONITORING FOR SAFETY OF RESEARCH PARTICIPANTS

The welfare of participants in clinical trials is overseen not just by IRBs and research ethics committees, which approve protocols before a trial can begin, but also by data and safety monitoring boards (DSMBs), which monitor data from ongoing trials, particularly large, multicenter trials.¹⁸¹ The role of DSMBs is to collect data that otherwise might not be aggregated until much later in a trial and to watch for unexpected adverse results that might necessitate halting the trial—or unexpected beneficial results that might justify making the experimental therapy more widely available.

Investigators should be vigilant in observing and reporting adverse events to their research ethics committees and other regulatory agencies. Although interpretation of individual adverse events may be problematic for IRBs, these ethics committees do need to conduct effective continuing reviews. DSMBs should review individual reported adverse events, as well as aggregate data on mortality rates or other outcome trends. By using preplanned statistical analyses, DSMBs can determine when trials should be stopped early to avoid continued exposure of participants to inferior treatments.

RESEARCH IN THE INTERNATIONAL CONTEXT

In September 2011, the U.S. Presidential Commission for the Study of Bioethical Issues published a review of U.S. Public Health Service-led studies in Guatemala involving the intentional exposure and infection of vulnerable populations that occurred between 1946 and 1948 during the study of penicillin to prevent and treat infection. The Commission concluded that “the experiments involved gross ethical violations.”¹⁸²

The Commission reviewed domestic and international contemporary human subjects protection rules and standards to ensure that federally funded scientific studies are conducted ethically.¹⁸³ This review was relevant as an increasing number of federally sponsored and pharmaceutical sponsored research is being performed in the developing world. Furthermore, commentators have recommended collaborations with colleagues in the developing world to address global disparities in critical illness and to care for those who become critically ill due to the consequences of natural disasters, acts of war, pandemics, and bioterrorism. Investigators and sponsors of such research need to ensure that it is not exploitative of the indigenous populations and is culturally sensitive.

COLLECTION AND STORAGE OF TISSUE SAMPLES FOR FUTURE UNSPECIFIED RESEARCH, PARTICULARLY GENETIC RESEARCH

Recent advances in genetics, molecular biology, and biomedical technologies have increased the scientific value of research on stored biologic samples and have spurred the development of genetic databases and biobanks. The collection, storage, and use of biologic samples in future research from acutely ill patients raise unique logistical and ethical challenges,¹⁸⁴ particularly regarding confidentiality, accuracy of substituted judgments, ownership, and the commercialization of stored biologic samples. There has also been a lack of consensus regarding the type and quality of

informed consent needed to collect and store samples for future, unspecified research.¹⁸⁵ Finally, as research has become increasingly globalized, ethical issues also arise from collaborative international research in which samples are collected in developing countries and then exported for analysis to developed countries.¹⁸⁶

RESPONSE TO DISASTER

Critical care practitioners may be called upon to participate in responding to natural and human-made disasters. As such they should be familiar with crisis standards of care developed by the Institute of Medicine (IOM)¹⁸⁷ and recommendations from the European Society of Intensive Care Medicine regarding benchmarks for management of critical illness when disasters occur. They are obliged to be well prepared with regard to key functions and assets including triage, infrastructure, essential equipment, sufficient personnel, protection of staff and patients, medical procedures, hospital policy, coordination and collaboration with interface units, registration and reporting, administrative policies, and education.¹⁸⁸ The IOM committee has argued that when crisis standards of care prevail, as when ordinary standards are in effect, health care practitioners must adhere to ethical norms. Conditions of overwhelming scarcity limit autonomous choices for both patients and practitioners regarding the allocation of scarce health care resources but do not permit actions that violate ethical norms. It has recognized that ethical considerations are one of the key elements of crisis standards of care protocols and that the most relevant ethical considerations are fairness, duty to care, duty to steward resources, transparency, consistency, proportionality, and accountability.¹⁸⁹

KEY POINTS

- The goals of the ICU team are to resolve life-threatening illness, to prolong life, and to relieve suffering.
- ICU providers should understand concepts of biomedical ethics including beneficence, nonmaleficence, autonomy, justice, truth telling, and confidentiality.
- When a diagnostic or therapeutic option is not medically indicated, a physician should not make it available.
- Given the likelihood that critically ill patients may be unable to participate in life-sustaining treatment decisions, clinicians should make efforts to promote advance care planning—use of advance directives—and should anticipate the need for limited treatment orders in advance of life-threatening events.
- Competent patients have the legal right to refuse medical treatments, even if physicians believe that such treatments are indicated. Patients do not, however, have a correlative right to demand treatment.
- Withholding or withdrawing life-sustaining treatment—with the informed consent of the patient or surrogate decision maker, or in compliance with advance

KEY POINTS (Continued)

- directives—is both valid and quite common. However, state laws regulating the authority of surrogate decision makers vary.
- Active euthanasia—for example, administering a fatal overdose of a narcotic with the express purpose of ending life—and physician-assisted suicide are illegal in most states but are the subject of intense ethical debate.
- Research lies outside the context of the doctor-patient relationship. In medical practice, physicians' primary obligation is to protect the best interests of their patients. Researchers have dual interests of advancing medical science and protecting the rights and welfare of human subjects. Physicians engaged in clinical research should make certain that their patients understand the difference.
- Heightened awareness of the principles and requirements that govern such research would enhance the ability of the research community to conduct such research ethically and to maintain the public trust in the research endeavor.
- Critical care practitioners should be prepared to coordinate care with other providers during disasters and should act ethically within the guidelines of crisis standards of care.

CONCLUDING THOUGHTS

OVERVIEW

An admission to the intensive care unit (ICU) is recognized by both the lay public and medical professionals to be a life-threatening event in most circumstances that is immediately made more distressing and sinister by the onset of delirium and severe sleep derangements during the ICU stay. Upon survival, however, these worries are often replaced over the ensuing months and years by mental health disturbances that can be crippling to survivors. We are now aware of the sometimes life-changing ramifications of brain and behavioral disorders that ICU survivors suffer. In the past 15 or so years, data have been published that clearly illustrate a spectrum of acquired or exacerbated “neck-up” disorders that often dismantle the lives of these patients and seriously delay their recovery. Most notable among these disorders is a potentially life-altering “dementia-like” brain injury that occurs in 60% to 80% of ICU survivors that is most often characterized by memory deficits and executive dysfunction. These problems have real-world implications because they diminish patients’ ability to work, drive, shop, monitor finances, and remember the names of their friends, relatives, and coworkers. These extremely troublesome neuropsychological deficits are compounded by mood disorders such as major depression and posttraumatic stress disorder

(PTSD). These two diagnoses (depression and PTSD) are underdiagnosed despite their occurrence in 20% to 30% and 10% to 20% of ICU survivors, respectively. As a profession, we are just beginning to address the risk factors for these newly acquired diseases.

Having acknowledged the preceding realities of the states of survival of critical illness, it is also true that advances in clinical medicine have resulted in dramatic improvements in survival in a host of medical conditions, such as acute respiratory distress syndrome (ARDS) and sepsis. In general, 1- to 3-month mortality rates for both of these common ICU admission diagnoses in most cohorts is now in the 20% to 35% range, whereas in the 1990s these mortality rates were in the 40% to 60% range. As a result of the increased confidence in survival, both the lay public and health care professionals are now increasingly focused on preservation of cognitive abilities, prevention of functional decline, and the quality of life among patients who survive critical illness.¹⁻⁵ The potential of being left cognitively impaired is a major determinant of patients’ treatment preferences at the end of life, with 9 of every 10 patients preferring death to severe cognitive impairment.⁶ In support of this reality, in a report from the international “Surviving Intensive Care” 2002 Roundtable Conference held in Brussels,⁷ the need for future investigations in neurocognitive abnormalities among survivors of intensive care received the

strongest recommendation from the international panel of experts. Physicians and health care providers in ICUs are accustomed to recognizing multiple organ dysfunction syndrome (MODS),⁸⁻¹¹ with therapy focused on the causes and treatment of respiratory, cardiovascular, renal, and hepatic dysfunction. There are increasing data on the syndrome of brain dysfunction during and following the ICU. This chapter focuses on the cognitive and mental health disturbances of critical illness, with emphasis on delirium and sleep disturbances during critical illness, as well as a brief discussion of PTSD, long-term cognitive impairment (LTICI), and depression after critical illness.

ACUTE BRAIN DYSFUNCTION OR DELIRIUM

DEFINITION

Delirium is defined by American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th revised edition (DSM-IV),¹² as a disturbance of consciousness with the cornerstone component of inattention¹³ being the pivotal feature of the diagnosis. This alarmingly common form of brain dysfunction often develops acutely (hours to days) in critically ill patients and fluctuates over time. Many different terms have been used to describe this spectrum of cognitive impairment in critically ill patients, including ICU psychosis, ICU syndrome, acute confusional state, septic encephalopathy, and acute brain failure.¹⁴⁻¹⁶ The current consensus of many authorities is to use the unifying term *delirium* and subcategorize according to the level of alertness (hyperactive, hypoactive, or mixed).¹⁷ We will take this approach in this chapter.

PREVALENCE AND SUBTYPES

Although the prevalence of delirium in medical ICU cohort studies has been reported to be between 20% and 80%,¹⁸⁻²⁰ more general ranges are practical depending on the severity of illness and the delirium detection instrument used, such as 40% to 60% in nonventilated and 60% to 80% in ventilated ICU patients.²¹ Unfortunately, because delirium is usually “quietly” manifested by negative symptoms, it remains unrecognized by the clinician in a majority of the patients experiencing this complication,^{22,23} and it may be incorrectly attributed to dementia, depression, or just an “expected” occurrence in the critically ill, elderly patient.²² Peterson and associates²⁴ reported on delirium subtypes from a cohort of ventilated and nonventilated ICU patients in whom delirium was monitored. They found the rates of these subtypes in the ICU to be 1.6% for hyperactive, 43.5% for hypoactive, and 54.1% for mixed.²⁵

Hyperactive delirium, which is rare in the pure form and associated with a better overall prognosis,²⁶ is characterized by agitation, restlessness, attempting to remove catheters or tubes, hitting, biting, and emotional lability.^{17,27} This subtype was in the past referred to by the misnomer “ICU psychosis.” Hypoactive delirium, on the other hand, is very common and in many circumstances actually more deleterious for the patient in the long run.²⁶ Unfortunately, it remains unrecognized in 66% to 84% of patients, whether being treated

in the ICU, hospital ward, or emergency department.^{23,28-30} This delirium subtype is characterized by withdrawal, flat affect, apathy, lethargy, and decreased responsiveness.^{26,31,32} Some authorities continue to refer to the hypoactive delirium as “encephalopathy” and the hyperactive subtype as “delirium or ICU psychosis.” Because of the fluctuating nature of delirium, patients may present with a mixed clinical picture or may sequentially experience both of these subtypes. Many critical care providers would have the incorrect impression that hyperactive delirium is far more common, perhaps because affected patients attract attention because of their immediate threat to self and others. Unless routine monitoring for delirium is implemented as part of an overall ICU bundle such as the ABCDEs (spontaneous Awakening trials, spontaneous Breathing trials, Coordination of care and Choice of sedative, Delirium monitoring and management, and Early mobility),^{33,34} the majority of delirium episodes, especially the “quiet” (hypoactive) form, will be missed.

PROGNOSTIC SIGNIFICANCE

In non-ICU populations, the development of delirium in the hospital is associated with an in-hospital mortality rate of 25% to 33%, prolonged hospital stay, and three times greater likelihood of discharge to a nursing home.³⁵⁻³⁷ In a three-site study of non-ICU medical patients, delirium was found to be an independent predictor of the combined outcome of death or nursing home placement.³⁸ McCusker and colleagues³⁹ found a 2.11 adjusted hazard ratio for dying in association with the development of delirium. This mortality rate increase has now been shown to be independent of dementia status.⁴⁰ Furthermore, three prospective studies have found that delirium was associated with a higher risk for dementia during the 2 to 3 years after hospitalization in non-ICU patient populations.⁴¹⁻⁴³

Among medical ICU patients, delirium has been shown to be a strong predictor of longer duration of mechanical ventilation, longer length of ICU stay, higher costs, prolonged neuropsychological dysfunction, and even death.⁴⁴⁻⁴⁷ The development of delirium was associated with a threefold increase in risk of death after data were controlled for preexisting comorbid conditions, severity of illness, coma, and the use of sedative and analgesic medications.⁴⁴ Three separate cohort studies have shown that the duration of delirium (in a dose-dependent sort of relationship) is an independent predictor of increased subsequent death, with the most commonly cited finding being that every day a patient spends in ICU delirium portends a 10% higher risk of death even after adjusting for relevant covariates such as severity of illness, age, psychoactive medication use, and coma.^{44,48,49} In addition, it is now shown that the duration of delirium is an independent predictor of LTICI in general medical and surgical ICU patients who in the past were not suspected of having long-term dementia-like abnormalities.⁵⁰

PATHOPHYSIOLOGY

The mechanisms of delirium remain a very promising area of neuroscientific study and likely relate to those factors leading to LTICI, which are as follows:

NEUROTRANSMITTERS

From a neuroscience perspective, delirium is thought to be related to imbalances in the synthesis, release, and inactivation of neurotransmitters modulating the control of cognitive function, behavior, and mood.^{26,32} Three of the neurotransmitter systems involved in the pathophysiology of delirium are dopamine, γ -aminobutyric acid (GABA), and acetylcholine.^{15,51,52} Whereas dopamine increases excitability of neurons, GABA and acetylcholine decrease neuronal excitability.¹⁵ An imbalance in one or more of these neurotransmitters results in neuronal instability and unpredictable neurotransmission. In general, an excess of dopamine and depletion of acetylcholine are two major physiologic problems believed to be central to delirium.⁵³ Other neurotransmitter systems thought to be involved in the development of delirium are serotonin imbalance, endorphin hyperfunction, and increased central noradrenergic activity.^{26,51}

INFLAMMATORY MEDIATORS

Other factors thought to be mechanistically deliriogenic in ICU patients are inflammatory abnormalities induced by endotoxins and cytokines.⁵⁴⁻⁵⁷ The inflammatory mediators produced in sepsis, such as tumor necrosis factor- α (TNF- α), interleukin 1, and other cytokines and chemokines, initiate a cascade that leads to endothelial damage, thrombin formation, and microvascular compromise.⁵⁸ Animal models show that these inflammatory mediators cross the blood-brain barrier,⁵⁹ increase vascular permeability in the brain,⁶⁰ and result in electroencephalography (EEG) changes consistent with those seen in septic patients with delirium.^{61,62} Release of inflammatory mediators may occur from (1) decreased cerebral blood flow, a result of the formation of microaggregates of fibrin, platelets, neutrophils, and erythrocytes in the cerebral microvasculature, (2) cerebral vasoconstriction occurring in response to α_1 -adrenergic receptor activity⁶³; or (3) interference with neurotransmitter synthesis and neurotransmission.⁶⁴

IMPAIRED OXIDATIVE METABOLISM

One hypothesis attempts to explain acute delirium as a behavioral manifestation of a “widespread reduction of cerebral oxidative metabolism resulting in an imbalance of neurotransmission.”⁶⁵ On the basis of a series of investigations in which they evaluated delirious patients using EEG, Engel and Romano⁶⁶ postulated that delirium is a state of “cerebral insufficiency,” that is, a global failure of cerebral oxidative metabolism. Their work showed that delirium is associated with diffuse slowing on EEG, a finding believed to represent a reduction in brain metabolism.

CHOLINERGIC DEFICIENCY

Blass and colleagues⁶⁷ offered a possible link between the state of cerebral insufficiency proposed by Engel and Romano⁶⁶ and the hypothesis of cholinergic blockade by suggesting that impaired oxidative metabolism in the brain results in a cholinergic deficiency. The finding that hypoxia impairs acetylcholine synthesis supports this hypothesis.⁶⁸ This reduction in cholinergic function leads to an increase in the level of glutamate, dopamine, and norepinephrine in the brain. Additionally, serotonin and GABA levels are reduced; all of these changes contribute to delirium.

LARGE NEUTRAL AMINO ACID IN DELIRIUM

Changes in the plasma levels of various amino acid precursors of cerebral neurotransmitters may affect their function, thus contributing to the development of delirium.⁶⁹ The amino acid entry into the brain is regulated by a sodium-independent large neutral amino acid transporter type 1 (LAT1).⁷⁰ The essential amino acid tryptophan, which is the precursor for serotonin, competes with several large neutral amino acids (LNAAs), such as tyrosine, phenylalanine, valine, leucine, and isoleucine, for transport across the blood-brain barrier via the LAT1 transporter.⁷⁰ This competition determines its uptake into the brain.⁷⁰ Recently, alterations in plasma tryptophan and tyrosine levels were identified as independent risk factors for the transition to clinical delirium.⁷¹ Increased activation of the kynurenine pathway, which is involved in the metabolism of tryptophan and the formation of neurotoxins, has also been linked to fewer days alive and without acute brain dysfunction in critically ill patients.⁷² Another amino acid that may play an important role in the pathogenesis of delirium is phenylalanine.⁶⁵ Like tryptophan, phenylalanine competes with the other LNAAs (tyrosine, tryptophan, valine, leucine, and isoleucine) for transport across the blood-brain barrier. An increase in the cerebral uptake of tyrosine and phenylalanine compared with the other LNAAs leads to greater availability of precursors for both dopamine and norepinephrine, two neurotransmitters that have been implicated in the pathogenesis of delirium.⁶⁵

INFLAMMATION

It is important to realize that although delirium may occur as a result of perturbations in other organ systems, the brain responds to systemic infections and injury with an inflammatory response of its own that also involves cytokine production, cell infiltration, and tissue damage.^{73,74} Reports indicate that local inflammation in the brain and subsequent activation of these central nervous system immune responses are accompanied by manifestations of systemic inflammation,^{52,75,76} including production of large amounts of peripherally produced TNF- α , interleukin 10, and interferon- γ .^{73,77-79} Thus, it is postulated that the brain can become an engine of inflammation, driving the development, resolution, or both, of MODS. Van Gool and associates propose that this self-propelling inflammation, in the context of microglial activation, could help explain the association between delirium and LTCI.⁸⁰ Surprisingly, van Gool points out that animal models have shown activated microglia can remain primed for months following injury, allowing ample time for ongoing injury long beyond the period of an ICU stay. This factors into hypothesis generation when designing neuroimaging studies in ICU survivors and will serve as fascinating topics for future study.

RISK FACTORS FOR DELIRIUM

Although non-ICU cohort studies have identified numerous risk factors for the development of delirium,³⁷ only a few studies have examined these factors in the ICU population. Baseline risk factors that predispose patients to a greater degree of vulnerability for delirium include Alzheimer's disease, chronic illness, advanced age, and depression.^{15,81,82} Dubois and coworkers⁸³ found that preexisting

hypertension and smoking (presumably because of relative hypoperfusion and nicotine withdrawal, respectively) were significantly associated with the development of ICU delirium. Another investigation reported that preexisting dementia was a significant risk factor for the development of delirium in the post-ICU period.¹⁹ A new area of investigation is genetic predisposition to delirium, as the apolipoprotein E4 polymorphism was found to predict delirium that lasted nearly twice as long as patients without the polymorphism.⁸⁴ Further studies have continued to suggest this association.⁸⁵

Precipitating and iatrogenic risk factors represent areas of potential modification and, thus, intervention for delirium prevention and treatment. Precipitating factors are hypoxia, metabolic disturbances, electrolyte imbalances, withdrawal syndromes, acute infection (systemic and intracranial), seizures, dehydration, hyperthermia, sleep deprivation, head trauma, vascular disorders, and intracranial space-occupying lesions.^{15,81,82}

In practical terms, the risk factors for delirium can be divided into the following categories: (1) host factors, (2) the acute illness itself, and (3) iatrogenic or environmental factors (Box 72.1). Although delirium may be a function of patients' specific underlying illness, it may also be due to medical management issues and thus may have preventable causes. Of these risk factors, sedative and analgesic medications and sleep deprivation appear to be the leading iatrogenic and hence possibly preventable risk factors for delirium. There are conflicting data on the association of anticholinergics, corticosteroids, histamine H₂ antagonists, and anticonvulsants with the development of delirium in ICU patients.^{22,86-88}

SEDATIVES AND ANALGESIC AGENTS CONTRIBUTING TO DELIRIUM

Sedative and analgesic medications are routinely administered to patients undergoing mechanical ventilation, in

accordance with widely recognized clinical practice guidelines by the Society of Critical Care Medicine (SCCM),⁸⁹ in order to reduce pain and anxiety. Investigations have shown that continuous intravenous sedation is associated with prolonged mechanical ventilation and greater morbidity.⁹⁰ Similarly, associations between psychoactive medications and worsening cognitive outcomes have been reported in postoperative patients. Marcantonio and colleagues,⁹¹ studying postoperative patients in whom delirium developed, found an association between use of benzodiazepines and meperidine and the occurrence of delirium. Dubois and coworkers⁸³ have shown that opiates (morphine and meperidine) administered either intravenously or via an epidural catheter may be associated with the development of delirium in medical/surgical ICU patients. Studies such as these have generated concern about whether such drugs were actually responsible for the development of delirium or were given as a result of delirium.

Our group has studied this temporal relationship between the administration of sedatives and analgesics and delirium.⁹² To do so, one must make repeated cognitive assessments and must be able to assess the risk factors a patient is exposed to in between these assessments in order to study which of these factors is associated with a transition or a change in cognitive status to or from normal, delirium, or coma. In our study, lorazepam was found to be an independent risk factor for daily transition to delirium, and fentanyl, morphine, and propofol were associated with higher but not statistically significant odds ratios for such transition (Fig. 72.1).⁹² Increasing age and APACHE II (Acute Physiology and Chronic Health Evaluation II) scores were also independent predictors of transitioning to delirium (Figs. 72.2 and 72.3).⁹² Similar associations between another benzodiazepine, midazolam, and transition to delirium have been found in another study conducted in our trauma and surgical ICU patients.²¹

Figure 72.1 Lorazepam dose versus probability of transitioning to delirium. The probability of transitioning to delirium increased with the dose of lorazepam administered in the previous 24 hours. This incremental risk was large at low doses and plateaued at around 20 mg/day. (From Pandharipande P, Shintani A, Truman P, et al: Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology* 2006;104:21-26. Used with permission from Lippincott Williams & Wilkins.)

Figure 72.2 Age versus the probability of transitioning to delirium. The most notable finding related to age was that probability of transitioning to delirium increased dramatically for each year of life after 65 years. (From Pandharipande P, Shintani A, Truman P, et al: Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology* 2006;104:21-26. Used with permission from Lippincott Williams & Wilkins.)

Figure 72.3 Severity of illness versus the probability of transitioning to delirium. The probability of transitioning to delirium increased dramatically for each additional point in APACHE II (Acute Physiology and Chronic Health Evaluation II) severity of illness score until it reached a plateau score of 18. (From Pandharipande P, Shintani A, Truman P, et al: Lorazepam is an independent risk factor for transitioning to delirium in intensive care unit patients. *Anesthesiology* 2006;104:21-26. Used with permission from Lippincott Williams & Wilkins.)

At this time it is not clear whether this association between benzodiazepines, and possibly opioids, and delirium is related to the pharmacokinetic properties of the agents or the pharmacodynamics of the drug. Benzodiazepines and propofol have high affinity for the GABA receptor in the central nervous system.⁹³ This GABA-mimetic effect can alter levels of numerous neurotransmitters believed to be deliriogenic.^{64,94} Novel sedative agents that are GABA receptor-sparing (such as the α_2 -agonists) may help reduce some of the cognitive dysfunction seen in ICU patients. It is important to note that the data for opioids and delirium are not as consistent as those for the benzodiazepines.

Although meperidine has been associated with delirium in most of the published studies, evidence for both fentanyl and morphine has been less convincing.^{83,91,95} Morrison and colleagues⁹⁵ conducted a prospective observational trial in patients who had undergone hip surgery and found that patients whose pain was well controlled with morphine were less likely to demonstrate delirium than those who received other opioids. These investigations point to the importance of the judicious use of psychoactive medications, with a focus on adequate analgesia.⁹⁶ One hopes that ongoing randomized controlled trials will pave the way to the development of sedation and analgesic guidelines for the prevention or reduction of the occurrence of delirium due to the administration of these psychoactive drugs.

DIAGNOSIS

The development of tools such as the Intensive Care Delirium Screening Checklist (ICDSC)¹⁸ and the Confusion Assessment Method for the ICU (CAM-ICU)²⁰ have allowed for the rapid diagnosis of delirium in patients by nonpsychiatric physicians and other health care personnel even while such patients are mechanically ventilated. The SCCM has proposed guidelines for more routine and more diligent monitoring of delirium using reliable and validated scales.⁸⁹

Diagnosis of delirium is a two-step process. Level of arousal is first measured with the use of a standardized sedation scale, like the Richmond Agitation-Sedation Scale (RASS) (Fig. 72.4).^{97,98} This is a 10-point scale with scores ranging from +4 to -5, score of 0 denoting a calm and alert patient. Positive RASS scores denote positive or aggressive symptomatology ranging from +1 (mild restlessness) to +4 (dangerous agitation). The negative RASS scores differentiate between response to verbal commands (scores -1 to -3) and physical stimulus (scores -4 and -5). If the patient's RASS score is -4 or -5 or not arousable by verbal commands, no further evaluation for delirium is performed, because the patient is comatose and is unable to be assessed for delirium. For patients who are arousable (RASS scores of -3 and higher), delirium can be assessed with the ICDSC¹⁸ or by the CAM-ICU.²⁰ The ICDSC assesses eight features of delirium: altered level of consciousness, inattention, disorientation, hallucinations, psychomotor agitation/retardation, inappropriate mood/speech, sleep/wake cycle disturbance, and symptom fluctuation. The sensitivity and specificity of this tool are 99% and 64%, respectively.¹⁸ The CAM-ICU, which can be performed in about 60 to 90 seconds,⁹⁹ comprises four features that assess the following: acute change or fluctuation of mental status (feature 1), inattention (feature 2), disorganized thinking (feature 3), and an altered level of consciousness (feature 4).

To be diagnosed as delirious, a patient must have a RASS score of -3 or higher, with an acute change or fluctuation in mental status (feature 1), accompanied by inattention (feature 2) and either disorganized thinking (feature 3) or an altered level of consciousness (feature 4). A complete description of the CAM-ICU as well as training materials, including translations and clinical vignettes, can be found at our website (www.icudelirium.org).

Recently, a meta-analysis evaluated the accuracy of the CAM-ICU and the ICDSC for the diagnosis of ICU delirium.¹⁰⁰ This investigation included nine studies evaluating

**Linking Sedation and Delirium Monitoring:
A Two-Step Approach to Assess Consciousness**

Step One: Sedation Assessment

The Richmond Agitation and Sedation Scale: The RASS

Score	Term	Description	
+4	Combative	Overly combative, violent, immediate danger to staff	
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive	
+2	Agitated	Frequent non-purposeful movement, fights ventilator	
+1	Restless	Anxious but movements not aggressive vigorous	
0	Alert and calm		
-1	Drowsy	Not fully alert, but has sustained awakening (eye-opening/eye contact) to voice (≥10 seconds)	} Verbal Stimulation
-2	Light sedation	Briefly awakens with eye contact to voice (<10 seconds)	
-3	Moderate sedation	Movement or eye opening to voice (but no eye contact)	} Physical Stimulation
-4	Deep sedation	No response to voice, but movement or eye opening to <i>physical</i> stimulation	
-5	Unarousable	No response to <i>voice or physical</i> stimulation	

If RASS is -4 or -5, then **Stop** and **Reassess** patient at later time.

If RASS is above -4 (-3 through +4), then **Proceed to Step Two**.

Step Two: Delirium Assessment

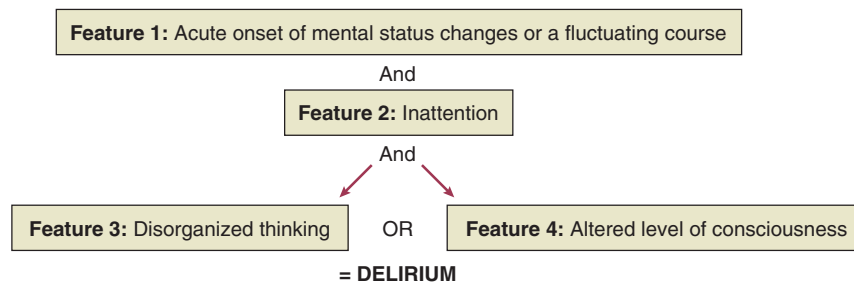

Figure 72.4 Richmond Agitation-Sedation Scale (RASS) and the Confusion Assessment Method for the ICU (CAM-ICU). This sedation scale and delirium instrument can be used together as a two-step approach to assess consciousness and diagnose delirium. Patients are considered to have delirium if they have RASS scores of -3 and higher and are assessed by CAM-ICU as “positive” by having both features 1 and 2 and either feature 3 or feature 4. (Data from references 19, 85, 86, and 148 [available online].)

the CAM-ICU ($N = 969$ total patients) and four studies evaluating the ICDSC ($N = 361$). The authors calculated the pooled sensitivity of the CAM-ICU to be 80% (95% confidence interval [CI]: 77.1-82.6%) and specificity of 95.9% (95% CI: 94.8-96.8%). The pooled sensitivity and specificity of the ICDSC were 74% (95% CI: 65.3-81.5%) and 81.9% (95% CI: 76.7-86.4%). They concluded that both delirium scales can be used as a screening tool, and that the CAM-ICU was an excellent diagnostic tool and the ICDSC had moderate sensitivity and good specificity.¹⁰⁰

PREVENTION AND MANAGEMENT

PRIMARY PREVENTION AND NONPHARMACOLOGIC APPROACHES

In a trial of 852 general medical patients older than 70 years,¹⁰¹ implementation of strategies for primary prevention of delirium resulted in a 40% reduction in the odds for development of delirium (15% in control subjects vs. 9.9% in the intervention patients). The protocol focused on optimization of risk factors via the following methods: repeated reorientation of the patient by trained volunteers and nurses, provision of cognitively stimulating activities for the patient three times per day, a nonpharmacologic sleep protocol to enhance normalization of sleep/wake cycles, early mobilization activities and range-of-motion exercises, timely removal of catheters and physical restraints, institution of the use of eyeglasses and magnifying lenses, use of hearing

aids and earwax disimpaction, and early correction of dehydration.¹⁰¹ Unfortunately, this intervention did not show sustained benefit during the 6 months of follow-up.¹⁰² Later studies of delirium were unable to reproduce this success in reducing the incidence of delirium.^{103,104}

Milisen and associates¹⁰⁵ and Lundstrom and coworkers,¹⁰⁶ who studied the implementation of multifactorial and multidisciplinary educational strategies, reported decreases in the duration and severity of delirium in patients cared for by staff who had received delirium-specific education.^{105,106} Milisen and associates¹⁰⁵ measured the impact on delirium of implementing a nurse-led intervention program that involved delirium education for the nursing staff, systematic cognitive screening, availability of consultative services from a delirium resource nurse, and scheduled pain protocol on delirium. These researchers reported that although the program had no effect on the incidence of delirium, the duration and severity of delirium were significantly lower.¹⁰⁵ Lundstrom and coworkers¹⁰⁶ reported that in patients on a ward where the staff participated in specific educational activities focused on delirium and where the bedside nursing care was reorganized to provide more continuity of patient-centered care, duration of delirium and hospital stay were shorter and mortality rate was lower than in control patients. Cole and colleagues¹⁰⁴ found no difference in delirium rates between patients cared for by an intervention nurse and patients who received standard care. All of these nonpharmacologic “protocolization of care” studies focused on

non-ICU patient populations. Clearly such investigations must be designed and conducted in the ICU (rather than simply extrapolated from non-ICU studies).

Although primary prevention of delirium is preferred, some delirium is inevitable in the ICU. In patients exhibiting delirium, the basic tenets of patient management, such as restoration of sleep/wake cycles, timely removal of catheters, early mobilization, minimization of unnecessary noise/stimuli, and frequent reorientation, should be applied liberally. Additionally, it should be emphasized that although sedative and analgesic agents have a very important role in patient comfort, health care professionals must also strive to achieve the right balance of administering these drugs through greater focus on reducing unnecessary or overzealous use. Instituting daily interruption of sedatives and analgesics, protocolizing their delivery, and instituting target-based sedation have all been shown to improve patient outcomes, although the studies reporting these results have not specifically looked at delirium rate or duration.¹⁰⁷⁻¹⁰⁹ Studies have also shown a benefit for pain control using morphine in the prevention of delirium, because pain itself can be a risk factor for the development of delirium. Family involvement can also be very helpful in reorienting and soothing some delirious patients. It is important to teach family members about the fluctuating course of delirium as well as how they can detect it. Preventive and management strategies for delirium in the ICU represent an important area for future investigation.

PHARMACOLOGIC THERAPY

Medications should be used for delirium only after adequate attention has been given to correction of modifiable contributing factors (e.g., sleep disturbance, restraints), as discussed previously. It is important to remember that delirium could be a manifestation of an acute, life-threatening problem that requires immediate attention (such as hypoxia, hypercarbia, hypoglycemia, metabolic derangement, or shock). After such concerns have been addressed, pharmacologic management should be considered. It should be recognized that although agents used to treat delirium are intended to improve cognition, they all have psychoactive effects that may further cloud the sensorium and promote a longer overall duration of cognitive impairment. Therefore, until we have outcomes data that confirm beneficial effects of treatment, these drugs should be used judiciously in the smallest possible dose and for the shortest time necessary, a practice infrequently adhered to in most ICUs. Indeed, some cases prove refractory to all “cocktail” approaches to sedation and delirium therapy, and in these cases, a trial of complete cessation of all psychoactive drugs should be considered. Some reports have described the utility of dexmedetomidine (an α_2 -agonist) as an adjunct to assist with weaning patients from all psychoactive medications.¹¹⁰ Preliminary results from a prospective, randomized, yet unblinded trial in postoperative patients who had undergone cardiac surgery showed that sedation with dexmedetomidine at sternal closure was associated with an 8% incidence of postoperative delirium compared with 50% for either propofol or benzodiazepines.¹¹¹

Benzodiazepines, which are used most commonly in the ICU for sedation, are not recommended for the management of delirium because of the likelihood of

oversedation, exacerbation of confusion, and respiratory suppression. However, they remain the drugs of choice for the treatment of delirium tremens (and other withdrawal syndromes) and seizures. The amnestic qualities of benzodiazepines make these agents especially useful when noxious or unpleasant procedures are required. It is likely, however, that residual accumulation of these drugs may lead to prolonged delirium long after they have been discontinued. In certain populations, particularly elderly patients with underlying dementia, benzodiazepines may increase confusion and agitation. In such cases, one may try to take advantage of the sedative effects of haloperidol in lieu of continuing the benzodiazepine therapy.

Currently, no drugs are approved by the U.S. Food and Drug Administration (FDA) for the treatment of delirium. The SCCM guidelines⁸⁹ recommend haloperidol as the drug of choice, with the acknowledgment that this recommendation is based on sparse outcome data from nonrandomized case series and anecdotal reports (i.e., level C data). Nevertheless, haloperidol is a “typical” butyrophenone antipsychotic, which is the most widely used neuroleptic agent for delirium.¹¹² It does not suppress the respiratory drive and works as a dopamine receptor antagonist by blocking the δ_2 -opioid receptor, resulting in treatment of positive symptoms (hallucinations, unstructured thought patterns, etc.) and producing a variable sedative effect. There are data to suggest that haloperidol may have some anti-inflammatory properties,^{113,114} though this is theoretical in terms of a helpful pharmacologic effect on disease (such as septic delirium) at this point and requires further study.

In the non-ICU setting, the recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, with repeated doses every 20 to 30 minutes until the desired effect is achieved. In the ICU, a recommended starting dose would be 2 to 5 mg every 6 to 12 hours (intravenous, intramuscular, or oral), with maximal effective doses usually in the neighborhood of 20 mg/day. This dose range will usually be adequate to achieve the “theoretically optimal” 60% δ_2 -receptor blockage¹¹⁵ while avoiding complete δ_2 -receptor saturation associated with the adverse effects cited later. Because of the urgency of the situation in many ICU patients—due to the potential for inadvertent removal of central lines, endotracheal tubes, or even aortic balloon pumps—much higher doses of haloperidol or a sedative are often used. Unfortunately, there are few data from formal pharmacologic investigations to guide dosage recommendations in the ICU. Once calm, the patient can usually be managed with much lower maintenance doses of haloperidol.

Neither haloperidol nor similar agents (i.e., droperidol and chlorpromazine) have been extensively studied for ICU use.⁸⁹ Newer “atypical” antipsychotic agents (e.g., risperidone, ziprasidone, quetiapine, and olanzapine) may also prove helpful for delirium.¹¹⁶ The rationale behind use of the atypical antipsychotics rather than haloperidol (especially in hypoactive/mixed subtypes of delirium) is theoretical and centers on the fact that they affect not only dopamine but also other potentially key neurotransmitters such as serotonin, acetylcholine, and norepinephrine.¹¹⁶⁻¹¹⁹ The use of haloperidol has been reported to have a mortality benefit in a retrospective analysis of critically ill, mechanically ventilated patients.¹¹⁴ Kalisvaart and associates¹²⁰ showed that

low-dose haloperidol prophylaxis reduced the duration and severity of delirium in elderly patients recovering from hip surgery, even though the actual prevalence of delirium was not reduced. A more recent study by Wang and coworkers¹²¹ also studied prophylactic haloperidol administration after cardiac surgery and actually did find a lower incidence of postoperative delirium associated with haloperidol, though this study was of a low severity of illness cohort and may not apply to truly critically ill patients with septic shock and ARDS. Skrobik and colleagues¹¹⁶ reported that olanzapine and haloperidol were equally efficacious in treating ICU delirium in both medical and surgical patients but that olanzapine had fewer side effects (again findings from a moderately ill group that must be confirmed and tested against placebo).

Adequately powered prospective, randomized placebo-controlled trials of antipsychotics are not available to date and must be performed to provide clinicians with evidence-based guidelines for preventing and treating delirium. Although there are prospective studies that begin to examine the safety and efficacy of antipsychotics such as amisulpride,¹²² quetiapine,¹²²⁻¹²⁴ and risperidone,^{125,126} these are generally small and quite heterogeneous in design population studied, dosing regimens, and the use of delirium assessment tools. A National Institutes of Health (NIH)-sponsored large prospective randomized placebo-controlled trial called MIND-USA is currently under way to investigate further the utility, risk, and benefit of both haloperidol and the atypical antipsychotic ziprasidone. The pilot study, called the MIND (Minimizing the Incidence of Delirium) trial,¹²⁷ established feasibility in a population of mechanically ventilated medical and surgical ICU patients and laid the groundwork for future research.

Kato and coworkers¹²⁸ reported a case study that suggests that genotyping may affect the choice of antipsychotic drugs. They showed that a patient with the CYP2D6 genotype had persistent delirium and demonstrated severe extrapyramidal symptoms when treated with risperidone. When quetiapine (metabolized by CYP3A4) was used instead, the patient's delirium cleared within 2 days without side effects. This case report is not proof of a positive effect of antipsychotics; yet it is interesting and suggests that pharmacogenetics may play an important role in medication choices in the near future.

Adverse effects of typical and atypical antipsychotics include hypotension, acute dystonias, extrapyramidal effects, laryngeal spasm, malignant hyperthermia, glucose and lipid dysregulation, and anticholinergic effects such as dry mouth, constipation, and urinary retention. Perhaps the most immediately life-threatening adverse effect of antipsychotics is torsades de pointes, and these agents should not be given to patients with prolonged QT intervals unless absolutely necessary. Patients who receive substantial quantities of typical or atypical antipsychotics or coadministered arrhythmogenic drugs should be monitored closely with electrocardiography. In early 2005, the FDA issued an alert that atypical antipsychotic medications are associated with a mortality risk among elderly patients. This warning was supported by a meta-analysis of a large volume of data from outpatient treatment of patients with dementia who were experiencing psychotic symptoms that resulted in their receiving antipsychotic medications.¹²⁹ Similar associations

with higher stroke risk and fatality have been reported by other investigators.^{130,131} Subsequently, other studies have suggested that this higher risk of death in non-ICU elderly patients treated with antipsychotics may not be limited to the atypical antipsychotic agents; Schneider and colleagues¹³⁰ found that the conventional antipsychotic haloperidol had an even higher mortality risk.

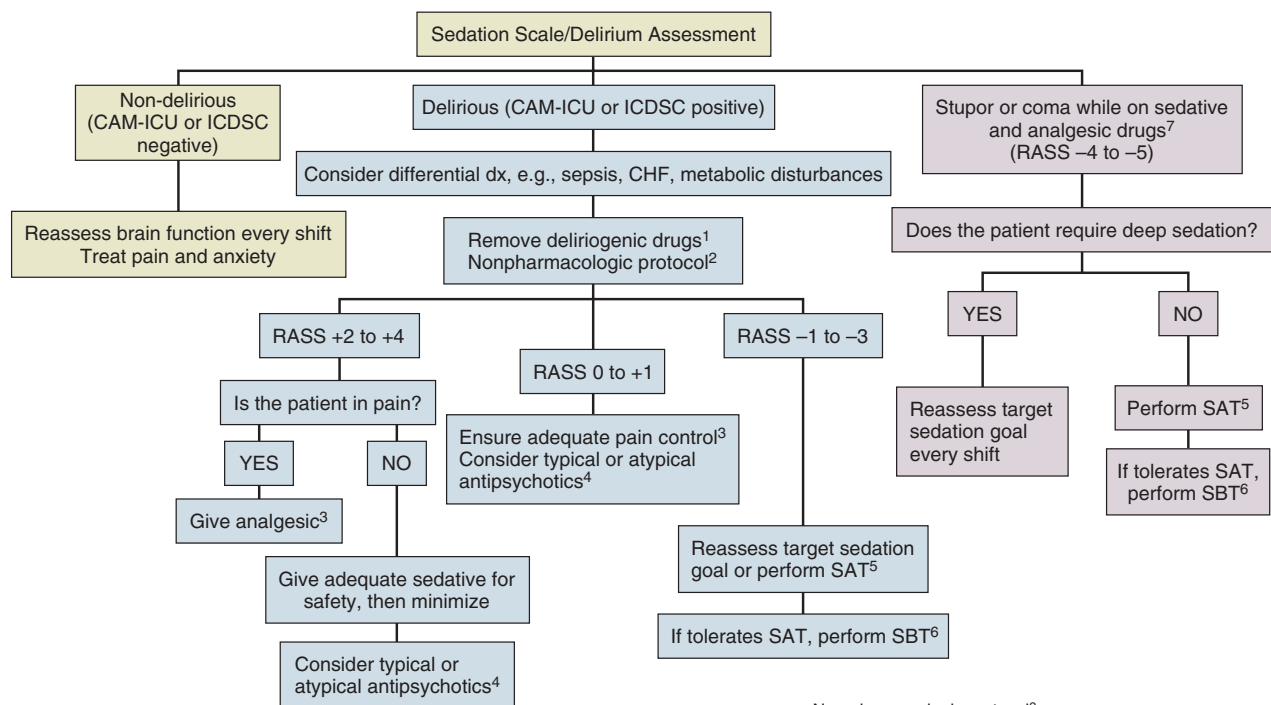

Along with haloperidol and the atypical antipsychotics for the treatment of acute brain dysfunction, a growing body of literature suggests a role for sedatives such as the α_2 -agonist dexmedetomidine in the pharmacologic management of delirium. The MENDS (Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction) trial¹³² compared dexmedetomidine to lorazepam for targeted sedation greater than 24 hours in 106 mechanically ventilated patients. Sedation with dexmedetomidine resulted in more days alive without coma or delirium and lower prevalence of coma compared to sedation with lorazepam. Subgroup analysis also demonstrated that sedation with dexmedetomidine reduced the daily risk of delirium, particularly in patients with sepsis.¹³³ The SEDCOM (Safety and Efficacy of Dexmedetomidine Compared with Midazolam) trial¹³⁴ compared dexmedetomidine to midazolam, another commonly used benzodiazepine in the ICU. This large prospective trial showed significantly lower prevalence of delirium in patients receiving dexmedetomidine compared to midazolam, an effect observed within 1 day of initiating sedation and sustained throughout the week of study drug administration.¹³⁴ In 2012, the MIDEX and PRODEX trials compared midazolam to dexmedetomidine (MIDEX) and propofol (preferred usual care) to dexmedetomidine (PRODEX) in mechanically ventilated patients requiring long-term sedation. These large trials, which together enrolled nearly 1000 patients, showed that dexmedetomidine was not inferior to midazolam or propofol for targeted light to moderate sedation and was found to be associated with improved communication between the patients and others involved in their care. Dexmedetomidine also reduced time to extubation and was associated with fewer neurocognitive disorders (including delirium) than propofol.¹³⁵ In each trial, the reproducible significant adverse effect associated with dexmedetomidine was bradycardia, which typically resolved without event and infrequently required adjunctive treatment beyond discontinuation of the drug.¹³⁵

Other agents such as the cholinesterase inhibitors have proved unsuccessful in the management of ICU delirium. Given the hypothesis that delirium was associated with excess dopamine and a central cholinergic deficiency, it was logical to test the cholinesterase inhibitors such as rivastigmine, used in treating dementia, for the management of ICU delirium. However, in 2010, a large placebo-controlled trial evaluating rivastigmine as an adjunct to usual care with haloperidol was halted early due to increased mortality risk and longer duration of delirium in patients receiving rivastigmine.¹³⁶ Other agents such as ondansetron¹³⁷ and melatonin¹³⁸ are being considered for the treatment of ICU delirium but thus far have little support in the literature.

Protocols and evidence-based strategies for prevention and treatment of delirium will no doubt emerge as more evidence becomes available from ongoing randomized clinical trials of both nonpharmacologic and pharmacologic

strategies. To assist readers in developing a delirium management algorithm in their respective clinical arenas, we have provided an empiric protocol largely based on the current SCCM clinical practice guidelines (Fig. 72.5). At this time, we have few data as to which antipsychotic medications are most suitable for delirium. The nonpharmacologic interventions recommended in this protocol have shown beneficial results in non-ICU patients, but the extrapolation to ICU populations is speculative. Nevertheless, such data emphasize the need for more research in this area and underscore the importance of exercising caution in the treatment of delirium. We wish to emphasize that protocols such as the ABCDEs of critical care^{33,34} must be updated regularly with new data and also individualized at each medical center to form an integrated approach to delirium monitoring, sedation targeting, and delirium management in critically ill ICU patients.

By way of summary regarding delirium management, the main thrust of our approach as health care professionals must begin with treatment of the underlying disease processes that are leading to brain dysfunction, then drug removal, and then modification of the environmental factors (hearing and vision aids, removal of restraints and early mobility, and sleep hygiene), which can be summarized via the mnemonic Dr. DRE (Diseases, Drug Removal, Environment). These are nicely summarized and operationalized in the evidence-based ABCDEs of ICU care, which stands for spontaneous Awakening trials, spontaneous Breathing trials, Coordination of care and Choice of sedative, Delirium monitoring and management, and Early mobility.^{33,34} Only after these issues are addressed is it appropriate to add another medication such as an antipsychotic into the mix of the individual pharmacopeia for any patient.

1. Consider stopping or substituting for deliriogenic medications such as benzodiazepines, anticholinergic medications (metoclopramide, H₂ blockers, promethazine, diphenhydramine), steroids, etc.
2. See non-pharmacologic protocol—at right
3. Analgesia—Adequate pain control may decrease delirium. Consider intermittent narcotics if feasible. Assess with objective tool.
4. Typical or atypical antipsychotics—While tapering or discontinuing sedatives, consider haloperidol 2 to 5 mg IV initially (0.5–2 mg in elderly) and then q 6 hours. Guideline for max haloperidol dose is 20 mg/day due to ~60% D₂-receptor saturation. May also consider using any of the atypicals (e.g., olanzapine, quetiapine, risperidone, ziprasidone, or aripiprazole). Discontinue if high fever, QTc prolongation, or drug-induced rigidity.
5. Spontaneous Awakening Trial (SAT)—Stop sedation or decrease infusion (especially benzodiazepines) to awaken patient as tolerated.
6. Spontaneous Breathing Trial (SBT)—CPAP trial if on ≤50% and ≤8 PEEP and Sats 90%
7. Sedatives and analgesics may include benzodiazepines, propofol, dexmedetomidine, fentanyl, or morphine.

Non-pharmacologic protocol²

Orientation

Provide visual and hearing aids
Encourage communication and reorient patient repetitively
Have familiar objects from patient's home in the room
Attempt consistency in nursing staff
Allow television during day with daily news
Non-verbal music

Environment

Sleep hygiene: Lights off at night, on during day. Sleep aids (zolpidem, mirtazapine)?
Control excess noise (staff, equipment, visitors) at night
Ambulate or mobilize patient early and often

Clinical parameters

Maintain systolic blood pressure >90 mm Hg
Maintain oxygen saturations >90%
Treat underlying metabolic derangements and infections

Figure 72.5 Delirium protocol. This empiric protocol, which is based largely on the current Society of Critical Care Medicine's clinical practice guidelines, is the algorithm we use to treat delirium in our intensive care units (ICUs). We wish to emphasize that such protocols need to be updated regularly with new data and also individualized at each medical center. Specific recommendations about the choice of antipsychotics to treat delirium have not been described, because limited data are available regarding the appropriate drug to use in ICU patients. The non-pharmacologic interventions recommended in this protocol have been shown to have beneficial results in non-ICU patients, but the extrapolation to ICU populations is speculative. SLEEP DISRUPTION IN THE CRITICALLY ILL

The sleep cycle is divided into rapid eye movement (REM) sleep and non-REM (NREM) sleep.¹³⁹ NREM sleep is further divided into four stages according to an increasing depth of sleep.¹¹¹ A normal sleep cycle lasts approximately 90 minutes, cycling continuously between REM and NREM sleep. Stages 3 and 4 of the NREM sleep represent slow-wave or more restful sleep.¹³⁹

Critically ill patients have severe sleep deprivation with disruption of sleep architecture. The average amount of sleep in the ICU has been measured to be about 2 hours out of 24 hours, with less than 6% of it spent in REM sleep. In a study by Cooper and associates,¹⁴⁰ the majority of the patients had abnormal sleep patterns. The causes of sleep deprivation in the ICU have been extensively reported. They consist of excessive noise and lighting, patient care activities such as procedures and baths, metabolic consequences of critical illness, mechanical ventilation, and the sedative and analgesic medications that are administered to these patients.¹⁴¹ This disturbance in duration and quality of sleep has detrimental effects on protein synthesis, cellular and humoral immunity, and energy expenditure, resulting in respiratory and hemodynamic effects as well as cognitive function.^{141,142} Studies that have looked at sleep disturbances due to noise, patient activities, and light have found that only about 30% of the sleep arousals were a result of these environmental factors, suggesting that other patient factors or management issues play an important

role.¹⁴³ Of these, it is interesting that the psychoactive medications are common risk factors for both delirium and sleep disturbances, whereas sleep deprivation can itself lead to delirium.

NEUROTRANSMISSION IN SLEEP

The ventrolateral preoptic (VLPO) nucleus in the anterior hypothalamus is the major area of the brain that controls sleep induction and maintenance.¹⁴⁴ Its major neurotransmitter is GABA, and during the awake state, the GABA release from the VLPO nucleus is inhibited by norepinephrine (NE) from the locus coeruleus.¹⁴⁴ With the inhibition of GABA, neurotransmitters such as orexin, serotonin, histamine, and acetylcholine are released, resulting in a state of wakefulness (Fig. 72.6). During NREM sleep, norepinephrine release diminishes, thus removing the inhibitory effect on release of GABA from the VLPO nucleus. The firing of GABA neurons inhibits the neurotransmitters of wakefulness (orexin, serotonin, histamine, and acetylcholine), resulting in NREM sleep (see Fig. 72.6). REM sleep, on the other hand, is facilitated by neurons in the pons that release acetylcholine. Studies show that serotonin and norepinephrine inhibit these neurons, suppressing REM sleep.

Sedative and analgesic medications are routinely administered to critically ill patients to promote sleep. However, although patients appear sedated, their sleep architecture is often adversely affected.¹³⁹ Benzodiazepines and propofol prolong stage 2 NREM sleep while decreasing slow-wave sleep and REM sleep. Opioids, on the other hand, increase

Figure 72.6 Neurotransmitter mechanism for wakefulness and non-rapid eye movement (NREM) sleep. The ventrolateral preoptic (VLPO) nucleus in the anterior hypothalamus is the major area of the brain that controls sleep induction and maintenance. Its major neurotransmitter is γ -aminobutyric acid (GABA), and during the awake state, GABA release from the VLPO nucleus is inhibited by norepinephrine (NE) from the locus coeruleus (LC). With the inhibition of GABA, neurotransmitters such as orexin (OX), serotonin (5-HT), histamine (His), and acetylcholine (ACh) are released, resulting in a state of wakefulness. During NREM sleep, there is a hierarchical sequence of changes in which inhibition of the LC disinhibits the VLPO nucleus to release GABA and galanin (Gal) at the projections that terminate at the tuberomammillary nucleus (TMN). These inhibitory neurotransmitters inhibit firing of the TMN projections to the cortical and subcortical regions. LDTg, laterodorsal tegmental nucleus; PPTg, pedunculopontine tegmental nucleus. (From Analgesics: Receptor ligands: Alpha 2 adrenergic receptor agonists. In Evers AS, Maze M: Anesthetic Pharmacology: Physiologic Principles and Clinical Practice. St. Louis, Churchill Livingstone, 2004. Used with permission from Dr. Mervyn Maze and Elsevier, Inc.)

stage 1 NREM sleep while decreasing slow-wave and REM sleep. It is hypothesized that one of the reasons that dexmedetomidine allows for less time in acute brain dysfunction (delirium) is that its effect in the locus coeruleus (rather than the VLPO nucleus, which is the site of action of benzodiazepines and propofol) leads to a more normal pattern of sleep. This effect has not been convincingly shown beyond animal models to date. Numerous other medications routinely administered to critically ill patients affect sleep architecture. These include antiarrhythmic agents, inotropes and vasopressors, antibiotics, antidepressants, steroids, anticonvulsants, and bronchodilators.¹³⁹ The effects of some of these compounds on sleep patterns are summarized in Table 72.1.

Although they lack anxiolytic properties, ω_1 -receptor agonists such as zolpidem may preserve REM as well as slow-wave sleep.¹⁴⁵ Similarly, mirtazapine, a noradrenergic and specific serotonergic antidepressant, has been studied in healthy volunteers and has been shown to improve sleep efficiency, reducing the number and duration of awakenings.¹⁴⁶ The slow-wave sleep time was also increased, whereas stage 1 sleep time was reduced significantly. This agent had no significant effect on REM sleep variables.¹⁴⁷ An investigation of the use of dexmedetomidine (an α_2 -agonist) in rats shows that it mimics and increases NREM sleep¹⁴⁴ but decreases REM sleep. By acting on the locus coeruleus, dexmedetomidine inhibits the release of norepinephrine, thus causing GABA output from the VLPO nucleus and inhibition of the neurotransmitters of wakefulness to produce a NREM sleep pattern. In contrast, benzodiazepines and propofol exert their sedative action on the VLPO

nucleus to increase GABA and decrease the neurotransmitters such as orexin, histamine, and serotonin but without affecting norepinephrine release from the locus coeruleus. Further clinical trials are required to ascertain the role of these medications in improving the quality and quantity of sleep in critically ill patients and to see whether such improvement may better the cognitive outcomes in ICU patients.

POSTTRAUMATIC STRESS DISORDER

DEFINITION AND DIAGNOSTIC CRITERIA

The DSM-IV¹² defines PTSD as a potentially debilitating psychiatric condition that develops as the result of exposure to a traumatic occurrence, in which the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others and that generates intense feelings of fear, helplessness, or horror in the person exposed to the trauma. This condition is characterized by a constellation of symptoms in the following three domains:

- Symptoms of reexperiencing (e.g., intrusive thoughts and upsetting recollections of the trauma, recurrent dreams or nightmares, and flashbacks)
- Symptoms of avoidance and emotional numbing (e.g., efforts to avoid conversations, places, and thoughts associated with the trauma; detachment from others; and a restricted range of affect)

Table 72.1 Drugs Commonly Used in the Intensive Care Unit and Their Effects on Sleep Patterns

Drug Class/Individual Drug	Sleep Disorder Induced/Reported	Possible Mechanism
Benzodiazepines	↓ REM, ↓ SWS	γ -Aminobutyric acid type A (GABA[A]) receptor stimulation
Opioids	↓ REM, ↓ SWS	μ -Opioid receptor stimulation
Clonidine	↓ REM	α_2 -Adrenergic receptor stimulation
Nonsteroidal anti-inflammatory drugs	↓ TST, ↓ SE	Prostaglandin synthesis inhibition
Norepinephrine/epinephrine	Insomnia, ↓ REM, ↓ SWS	α_1 -Adrenergic receptor stimulation
Dopamine	Insomnia, ↓ REM, ↓ SWS	δ_2 -Opioid receptor stimulation/ α_1 -adrenergic receptor stimulation
β -Blockers	Insomnia, ↓ REM, nightmares	Central nervous system β -blockade by lipophilic agents
Amiodarone	Nightmares	Unknown mechanism
Corticosteroids	Insomnia, ↓ REM, ↓ SWS	Reduced melatonin secretion
Aminophylline	Insomnia, ↓ REM, ↓ SWS, ↓ TST, ↓ SE	Adenosine receptor antagonism
Quinolones	Insomnia	GABA(A) receptor inhibition
Tricyclic antidepressants	↓ REM	Antimuscarinic activity and α_1 -adrenergic receptor stimulation
Selective serotonin reuptake inhibitors	↓ REM, ↓ TST, ↓ SE	Increased serotonergic activity
Phenytoin	↑ Sleep fragmentation	Inhibition of neuronal calcium influx
Phenobarbital	↓ REM	Increased GABA(A) activity
Carbamazepine	↓ REM	Adenosine receptor stimulation and/or serotonergic activity

REM, rapid eye movement (sleep); SE, sleep efficiency; SWS, slow-wave sleep; TST, total sleep time.

Reproduced with permission from Bourne RS, Mills GH: Sleep disruption in critically ill patients—Pharmacological considerations. *Anaesthesia* 2004;59:374-384.

- Symptoms of increased arousal (e.g., sleep disruption, hypervigilance, and exaggerated startle response)

These symptoms must meet two criteria to be diagnosed as PTSD, as follows:

1. Symptoms must cause significant impairment in social, occupational, or other important functional domains.
2. Symptoms must be present for at least 1 month after exposure to the traumatic event or events.

PREVALENCE OF ICU-RELATED POSTTRAUMATIC STRESS DISORDER

The prevalence rates reported in studies on PTSD after critical illness vary widely (5% to >50%) and differ according to whether the specific outcome in question is a diagnosis of PTSD or merely the presence of PTSD symptoms. In the eight investigations that focused on the identification of subjects with PTSD (as opposed to those with PTSD symptoms), prevalence rates ranged from 9.7% to approximately 40%.¹⁴⁷ The prevalence of PTSD differed depending on the time of assessment, with higher rates identified in closer proximity to the time of hospital discharge. In investigations that included serial evaluations, patients generally demonstrated a decrease in symptoms over time. For example, Kapfhammer and colleagues¹⁴⁸ reported that 43.5% of study subjects had PTSD at discharge (although according to the DSM-IV, PTSD cannot be diagnosed until 4 weeks after exposure to the “traumatic stressor”), whereas 23.9% suffered from PTSD an average of 8 years later. Prevalence rates tend to be higher among some specific ICU populations, such as patients with sepsis or ARDS (25% to 40% at follow-up), in comparison with general medical ICU cohorts.¹⁴⁸

RISK FACTORS FOR POSTTRAUMATIC STRESS DISORDER

A number of subject characteristics appear to raise the risk of PTSD symptoms or an actual diagnosis of PTSD, although consensus among the studies reviewed is limited. Reported risk factors include delusional memories of the ICU, a greater number of traumatic memories of the ICU, longer ICU length of stay or duration of mechanical ventilation or both, younger age, prior mental health history, female gender, and higher levels of sedation and neuromuscular blockade.¹⁴⁹ No studies have investigated the association between delirium and PTSD.

CONCEPTUAL EXPLANATIONS FOR POSTTRAUMATIC STRESS DISORDER AFTER CRITICAL ILLNESS

Although the stresses associated with ICU hospitalization may differ from events typically described as “traumatic experiences,” there are a variety of conceptual explanations for the development of PTSD following critical illness. They include (1) profound feelings of helplessness associated with the experience of critical illness, (2) high rates of pre-existing psychiatric morbidity that may characterize ICU patients,¹⁵⁰ (3) cognitive impairment, including decreased

working memory, which may limit individual abilities to suppress intrusive thoughts,¹⁵⁰ and (4) multiple traumatic episodes associated with anxiety, panic, or pain that occur during ICU hospitalization, such as intubations, extubations, nightmares, and respiratory distress.^{151,152}

The frequency of anxiety-provoking episodes during ICU hospitalization might partly explain the association between higher levels of sedation and increased PTSD symptoms, in that anxious patients may receive more sedatives. Brewin and Holmes¹⁵³ suggest that immobilization with incomplete sedation promotes a dissociative experience that may be a PTSD risk factor.

A significant percentage of patients treated in the ICU have chronic medical illnesses,^{154,155} which may increase anxiety or susceptibility to anxiety reactions. The presence of such stressors may have a cumulative effect on an individual’s coping resources, leading to a greater vulnerability to PTSD. This concept is bolstered by evidence from numerous studies as well as the theoretical work of Turner and Lloyd,¹⁵⁶ which supports the notion that healthy coping responses are impeded by the “accumulated burden of adversity” associated with illness or disease.¹⁵⁷⁻¹⁵⁹ Although the contribution of cumulative illness to the development of PTSD has not been assessed in ICU populations, investigations support an association between accumulated medical burden and higher risk of PTSD. For example, accident victims (without chronic medical illnesses) who are admitted to the trauma ICU have a lower prevalence of PTSD than their medical ICU counterparts (with multiple chronic diseases).¹⁶⁰ Alternatively, patients with chronic cardiovascular disease who have undergone cardiac surgery have relatively high rates of PTSD, which correlate positively with preoperative disease severity.¹⁵¹

The relationship between cognitive function and PTSD is a subject of ongoing debate, particularly as it relates to the role of memory in mediating the development of PTSD.¹⁶¹ The importance of specific, explicit memories (memories pertaining to facts and events, which are accessible to consciousness)^{162,163} in the generation and maintenance of PTSD is difficult to estimate because they are the basis for nightmares, flashbacks, and intrusive thoughts and contribute to symptoms of avoidance and reexperiencing. Although a detailed treatment of these issues is beyond the scope of this chapter, we briefly discuss several key findings from the literature as they relate to ICU populations.

The preponderance of evidence suggests that the absence of episodic memory for a traumatic event is protective against the development of PTSD, because a majority of studies have shown that the risk of PTSD is markedly lower in individuals unable to recall a traumatic event than in those with explicit memory of it.¹⁶⁴⁻¹⁶⁸ The literature is not unanimous and is narrow in scope, with virtually all relevant studies having been conducted on victims of motor vehicle accidents or other traumas with concomitant traumatic brain injury.¹⁶⁹ Theories of information processing suggest that traumatic memories can be encoded implicitly during periods of impaired consciousness and may provide the basis for the generation of PTSD symptoms even if patients are not consciously aware of the memories.¹⁷⁰⁻¹⁷³ Additionally, during periods of impaired consciousness, the encoding of emotional experiences such as panic and severe pain appears to be sufficient for the generation of PTSD symptoms.¹⁷⁴

Many ICU patients report little if any conscious awareness of their critical illness, although as Jones and associates¹⁷⁵ have reported, delusional memories, often with violent and paranoid themes, are pervasive among such patients. Distorted and fragmentary memories may be vestiges of the nightmares, hallucinations, or delusions induced by critical illness, a variety of medications, or other causes and may be particularly likely to occur during delirium, which is ubiquitous in critically ill, mechanically ventilated patients.^{16,176} Sedative medications may constitute one factor that mediates the development of delusional memories.¹⁷⁷ Delusional memories may exist in the absence of factual memories, which provide markers of reality and may serve to orient the patient. For example, daily sedative interruption has been found to be associated with fewer symptoms of PTSD,¹⁷⁸ suggesting that even limited factual memories from brief awakening may reduce PTSD. In addition, delusional memories tend to be stable over time and are significantly more persistent than factual memories.¹⁷⁹ Delusional memories may be more refractory to the normal cognitive processes of habituation and reappraisal because they are not well integrated into the long-term memory. Although research is limited, the presence of delusional memories of the ICU is associated with higher levels of anxiety and PTSD.^{180,181}

LONG-TERM COGNITIVE IMPAIRMENT AFTER CRITICAL ILLNESS

Medical and surgical management of critical illnesses can, and frequently does, result in *de novo* neurocognitive impairments. Approximately one third or more of ICU survivors have LTCI.¹⁸² It is difficult to make comparisons among studies owing to differences in definitions of neurocognitive sequelae, administered neuropsychological tests, time to follow-up, patient population, study design (prospective vs. retrospective), and inclusion of a control group. Nevertheless, current data suggest that neurocognitive impairments are extremely common in survivors of critical illness.

Currently, 10 cohort studies totaling approximately 455 patients have assessed LTCI after critical illness.¹⁸²⁻¹⁹² The populations of the patient cohorts include patients with ARDS, acute lung injury, and respiratory failure in the ICU^{182,183,187,189-192} as well as two studies in general ICU patients.^{184,188} The time to neurocognitive assessments was variable, with the majority occurring during the first year after hospital discharge. Three studies assessed patients more than 1 year later. A prospective longitudinal study monitored patients at hospital discharge and then at 1 and 2 years after hospital discharge,¹⁹³ and two retrospective studies assessed the patients at approximately 6 years after hospital discharge.^{187,191}

The evidence from the 10 cohorts suggests that 25% to 78% of ICU survivors experience neurocognitive impairments.¹⁸²⁻¹⁹² Among specific populations, such as patients with ARDS, the prevalence of LTCI is even greater; it may be as high as 78% at hospital discharge, 46% at 1 year,¹⁸³ and 25% at 6 years.¹⁹¹ Hopkins and colleagues¹⁸³ assessed ARDS patients' premorbid estimated intelligence quotient (IQ) and found it was significantly higher than the patients' measured IQ at hospital discharge. However, the

patients' measured IQ improved to their premorbid level by 1-year follow-up, with no additional improvement at 2 years. The finding that patients recovered over time with regard to intelligence does not necessarily suggest a comparable recovery in all cognitive domains, because data from traumatic and anoxic brain injury literature suggest that some neurocognitive abilities are more likely to improve than others.¹⁹⁴

A 2004 study found that neurocognitive impairments occur in 70% of ARDS patients at hospital discharge, 45% at 1 year, and 47% at 2 years.¹⁹³ The neurocognitive test scores of the ARDS survivors with neurocognitive sequelae ($\approx 50\%$ of survivors) fell below the sixth percentile of the normal distribution of cognitive function. These ARDS survivors had marked difficulty with tasks that require executive function, memory, attention, or quick mental processing. The neurocognitive impairments in critically ill patients are similar to those reported in medical ICU survivors¹⁸² after carbon monoxide poisoning¹⁹⁵ and several years after elective coronary artery bypass graft surgery.¹⁹⁶

In addition to ARDS survivors, neurocognitive impairments have been reported in the general population of critically ill patients. Jackson and colleagues,¹⁸² evaluating 34 medical ICU survivors at 6 months, found that 33% had LTCI (using a very conservative definition of impairment as two test scores 2 standard deviations below the mean or three test scores 1.5 standard deviations below the mean). The neurocognitive impairments were similar to those reported in ARDS survivors; they included mental processing speed, memory, language, and visuospatial abilities. Additional support for cognitive impairment in the general critically ill population comes from a prospective cohort of 32 critically ill patients who underwent long-term mechanical ventilation (>5 days). The patients were evaluated at hospital discharge and 6 months later.¹⁸⁵ Of the patients who received long-term mechanical ventilation, 91% at hospital discharge and 41% at 6 months had impairments in attention, memory, mental processing speed, and executive function.¹⁸⁵

Girard and colleagues showed that the duration of delirium was an independent predictor of LTCI at 1-year follow-up even after adjusting for relevant covariates.⁵⁰ It is hoped that other ongoing investigations will provide information about the risk factors for the development of LTCI and help guide interventions for prevention of the rather debilitating sequelae of critical illness that affect a person's quality of life.

DEPRESSION

Many ICU survivors experience significant affective symptoms, such as depression and anxiety.¹⁹⁷ The prevalence and severity of affective disorders, including symptoms of depression and anxiety in ICU survivors, range from less than 10% to 58%.^{147,182,183,190,198} Depression has been reported to occur in up to 30% of ICU survivors,¹⁸² and it is estimated that 47% have clinically significant anxiety.¹⁹⁷ Indeed, the high rates of depression among ICU survivors may be related to the cognitive impairment they experience, although this issue has not been evaluated in ICU cohorts. Affective disorders such as depression, PTSD, and anxiety may adversely

affect test performance, especially if severe.^{199,200} Moderate to severe depression may result in decreased effort and low motivation, which may in turn lower neuropsychological test scores in cognitive domains such as psychomotor speed and attention.^{201,202} Moderate to severe anxiety, however, may lead to increased distractibility and blocked thoughts or words.^{203,204} In some cases, severe depression may mimic symptoms of cognitive impairment, although there are important differences between these conditions. In general, individuals with depression retain the ability to learn and do not forget as rapidly, do not display significant decrements in language, are inconsistent with regard to orientation to time and date, and are typically more self-aware than their cognitively impaired counterparts.²⁰⁵⁻²⁰⁷

A variety of instruments are available for use in the assessment of affective function. Tools such as the Geriatric Depression Scale-Short Form (GDS-SF),²⁰⁸ the Beck Depression Inventory (BDI),²⁰⁹ the Center for Epidemiologic Studies Depression Scale (CES-D),²¹⁰ and the Hospital Anxiety-Depression Scale (HADS)²¹¹ assess depression. Anxiety can be assessed with the HADS²¹¹ or the Beck Anxiety Inventory (BAI).²¹² Discussion of these tools is beyond the scope of this chapter.

CONCLUDING THOUGHTS

How might we incorporate these issues into our life as a health care professional? It is important as you see patients being newly admitted to the ICU with diseases such as severe sepsis or an exacerbation of COPD to remind yourself that during subsequent days under your care, these patients will acquire new “neck-up” and “neck-down” (brain plus neuromuscular) diseases. It is imperative that these two new elements of disease burden become a major focus of medical attention during and following these patients’ ICU stays. It is also important to recognize that these two categories of disability are inextricably linked. As we work to identify methods of intervention to prevent and treat these disabilities, it may be helpful to focus on modifiable aspects of care such as reducing total exposure to psychoactive medications, reducing duration of delirium, mitigating sleep deficits and derangements, and minimizing periods of immobilization.

KEY POINTS

- Delirium is a disturbance of consciousness heralded by the cardinal manifestation of inattention, accompanied by a change in cognition or perceptual disturbance that develops over a short time and has a fluctuating course.
- The prevalence of delirium in medical and surgical ICU studies has been reported to be 60% to 80% in cohorts restricted to those receiving mechanical ventilation and around 40% to 60% in ICU cohorts of nonventilated patients.

KEY POINTS (Continued)

- Delirium is an independent predictor of longer duration of mechanical ventilation, longer ICU stays, higher costs, and a threefold higher risk of dying within 6 months or an increase of 10% risk of death per day of delirium.
- The development of tools such as the ICDSC and the CAM-ICU have allowed for the rapid diagnosis of delirium in patients by nonpsychiatric physicians and health care personnel even during mechanical ventilation.
- Sedative and analgesic medications and sleep disturbances in the ICU may be modifiable risk factors of delirium.
- The main thrust of delirium management must begin with treatment of the underlying disease processes that are leading to brain dysfunction, then drug removal (not addition), and then modification of the environmental factors (hearing and vision aids, removal of restraints and early mobility, and sleep hygiene). Summarize these via the mnemonic Dr. DRE. These are nicely summarized and operationalized in the evidence-based ABCDEs of ICU care.
- Only after these issues are addressed is it appropriate to add another medication such as an antipsychotic into the mix of the individual pharmacopeia for any patient. Which medication to add (e.g., antipsychotic) is a point of ongoing investigation.
- Critically ill patients often have severe sleep deprivation with disruption of sleep architecture that is made worse by most sedative medications.
- The average amount of sleep in ICU patients has been measured to be about 2 hours in a 24-hour period, less than 6% of which is REM sleep often because of REM suppression from medications such as benzodiazepines and propofol.
- PTSD is a potentially debilitating psychiatric condition, which develops in 5% to 50% of ICU survivors as the result of exposure to a traumatic occurrence that generates intense feelings of fear, helplessness, or horror.
- Medical and surgical management of critical illnesses is associated with long-term neurocognitive impairments in approximately two thirds of ICU survivors. This form of cognitive impairment mimics dementia in many patients as they suffer from moderate to severe deficits in memory, executive dysfunction, and other domains with profound ecologic validity.
- Between one third and two thirds of ICU survivors experience significant affective symptoms, such as depression and anxiety, which serve as another ongoing aspect of suffering that all too often remains undiagnosed and therefore unaddressed by the medical teams caring for ICU survivors.

Severity of Illness Scoring Systems

Rui Moreno

When you can measure a phenomenon about which you are talking and express it in numbers, you know something about it. But, when you can not express it in numbers, your knowledge is vague and unsatisfactory. It may be the beginning of knowledge, but you progressed very little toward the state of science.

LORD KELVIN (1824-1907)

CHAPTER OUTLINE

HISTORICAL PERSPECTIVE

SEVERITY OF ILLNESS ASSESSMENT AND OUTCOME PREDICTION

Recalibrating and Expanding Existing Models

Building New Models

DEVELOPING PREDICTIVE MODELS

Selecting the Target Population

Outcome Selection

Data Collection

Selection of Variables

Validation of the Model

Updating Severity Scores

Using a Severity of Illness Score

Application of a Severity of Illness Score: Evaluation of Patients

ORGAN DYSFUNCTION/FAILURE SCORING SYSTEMS

Multiple Organ Dysfunction Score

Sequential Organ Failure

Assessment Score

Logistic Organ Dysfunction System Score

Comparison of the Described Systems

SCORING SYSTEMS FOR SPECIFIC CLINICAL CONDITIONS

DIRECTIONS FOR FURTHER RESEARCH

The goal of intensive care is to provide the highest quality of treatment in order to achieve the best outcomes for critically ill patients. Although intensive care medicine has developed rapidly over the years, there exists, still, little scientific evidence as to what treatments and practices are really effective in the real world. Moreover, intensive care now faces major economic challenges, which increase the need to provide evidence not only on the effectiveness but also on the efficiency of practices. Intensive care is, however, a complex process, which is carried out on very heterogeneous populations and is influenced by several variables, including cultural background and different structure and organization of the health care systems. It is, therefore, extremely difficult to reduce the quality of intensive care to something measurable, to quantify it and then to compare it among different institutions. Also, in recent years, patient safety as a necessary dimension in the evaluation of quality of the care provided has become mandatory, leading to major changes in the way benchmarking should be evaluated and reported.¹

Although quality encompasses a variety of dimensions, the main interest to date is focused on effectiveness and efficiency: It is clear that other issues are less relevant if the care being provided is either ineffective or harmful.

Therefore, the priority must be to evaluate effectiveness. The instruments available to measure effectiveness in intensive care derive from the science of outcome research. The starting point for this science was the high degree of variability in medical processes, which was found during the first part of the twentieth century, when epidemiologic research was developing. The variation in medical practices led to the search for the “optimal” therapy for each syndrome or disease through the repeated performance of randomized controlled trials (RCTs). However, the undertaking of RCTs in intensive care is fraught with ethical and other difficulties. For this reason, observational studies to evaluate the effects of intensive care treatment are still frequently employed and sometimes more informative than prior RCTs.² Outcome research provides the methods necessary to compare different patients or groups of patients, especially different institutions. Risk adjustment (also called case-mix adjustment) is the method of choice to standardize the severity of illness of the individual or groups of patients. The purpose of risk adjustment is to take into account all of the characteristics of patients known to affect their outcome, in order to understand the differences due to the treatment received and the conditions (timing, setting, standardization) in which that treatment has been delivered.

Conceptually, the quantification of individual patients should be made by the use of severity scores, and the evaluation of groups of patients is done by summing up the probabilities of death given by the model for each individual patient and its comparison with actual fatality.

This chapter intends to describe the different methods and systems that are available for the purpose of accessing and comparing severity of illness and outcome in critically ill patients. Starting with a brief historical outline of the development of scoring systems over time, the reader should then become familiar with the way such systems have been designed and constructed. In succession, the chapter will describe available systems with their applications and limitations. Finally, the text will focus on the potential applications of these systems at both the patient level and the intensive care unit (ICU) level.

HISTORICAL PERSPECTIVE

Scoring systems have been broadly used in medicine for several decades. In 1953 Virginia Apgar³ published a very simple scoring tool, the first general severity score designed to be applicable to a general population of newborn children. It was composed of five variables, easily evaluated at the patient's bedside, that reflect cardiopulmonary and central nervous system function. Its simplicity and accuracy have never been improved on, and any child born in a hospital today receives an Apgar score at 1 and 5 minutes after birth. Nearly 50 years ago Dr. Apgar commented on the state of research in neonatal resuscitation: "Seldom have there been such imaginative ideas, such enthusiasms and dislikes, and such unscientific observations and study about one clinical picture." She suggested that part of the solution to this problem would be a "simple, clear classification or grading of newborn infants which can be used as the basis for discussion and comparison of the results of obstetric practices, types of maternal pain relief and the effects of resuscitation." Thirty years later, physicians working in ICUs found themselves using the same tools and applying them in the same way.

Efforts to improve risk assessment during the 1960s and 1970s were directed at improving our ability to quickly select those patients most likely to benefit from promising new treatments. For example, Child and Turcotte⁴ created a score to measure the severity of liver disease and estimate mortality risk for patients undergoing shunting. In 1967, Kilipp and Kimball classified the severity of acute myocardial infarction by the presence and severity of signs of congestive heart failure.⁵ In 1974 Teasdale and Jennett introduced the Glasgow Coma Scale (GCS) for reproducibly evaluating the severity of coma.⁶ The usefulness of the GCS score has been confirmed by the consistent relationship between poor outcome and a reduced score among patients with a variety of diseases. The GCS score is reliable and easy to perform, but problems with the timing of evaluation, the use of sedation, inter- and intraobserver variability, and its use in prognostication have caused strong controversies.⁷ Nevertheless, the GCS remains the most widely used neurologic measure for risk assessment.

The 1980s brought an explosive increase in the use of new technology and therapies in critical care. The rapidity

of change and the large and growing investment in these high-cost services prompted demands for better evidence for the indications and benefit of critical care. For this reason several researchers developed systems to evaluate and compare the severity of illness and outcome of critically ill patients. The first of these systems was the Acute Physiology And Chronic Health Evaluation (APACHE) system, published by Knaus and associates in 1981,⁸ followed soon after by Le Gall and colleagues with the Simplified Acute Physiology Score (SAPS).⁹ The APACHE system was latter updated to APACHE II,¹⁰ and a new system, the Mortality Probability Model (MPM), joined the group.¹¹ By the beginning of the 1990s different systems were available to describe and classify ICU populations, to compare severity of illness, and to predict mortality risk in their patients. These systems performed well, but there were concerns about errors in prediction caused by differences in patient selection and lead-time bias. There were also concerns about the size and representativeness of the databases used to develop the three systems and about poor calibration within patient subgroups and across geographic locations. These concerns, in part, led to the development of their subsequent versions such as APACHE III,¹² the SAPS II,¹³ and the MPM II,¹⁴ all published between 1991 and 1993.

During the mid-1990s, the need to quantify not only mortality but also morbidity risks in specific groups of patients became evident and led to the development of the so-called organ dysfunction scores, such as the Multiple Organ Dysfunction Score (MODS),¹⁵ the Logistic Organ Dysfunction System (LODS) score,¹⁶ and the Sequential Organ Failure Assessment (SOFA) score.¹⁷

SEVERITY OF ILLNESS ASSESSMENT AND OUTCOME PREDICTION

The evaluation of severity of illness in the critically ill patient is made through the use of severity scores and outcome prediction models. This distinction is crucial to understanding the differences, limitations of use, and aims of each one.

- Severity scores are instruments that aim at stratifying patients based on their severity, assigning to each patient an increasing score as the severity of the illness increases.
- Outcome prediction models, apart from their ability to stratify patients according to their severity, aim at predicting a certain outcome (usually the vital status at hospital discharge) based on a given set of prognostic variables and a certain modeling equation.

The development of this kind of system, applicable to heterogeneous groups of critically ill patients, started in the 1980s (Table 73.1). The first general severity of illness score applicable to most critically ill patients was the APACHE score.⁸ Developed in the George Washington University Medical Center in 1981 by William Knaus and coworkers, the APACHE system was created to evaluate, in an accurate and reproducible form, the severity of disease in this population.¹⁸⁻²⁰ Two years later, Jean-Roger Le Gall and coworkers published a simplified version of this model, the SAPS.²¹ This model soon became very popular in Europe, especially in France. Another simplification of the original

*These models are based on previous versions, developed by the same investigators (Lemeshow et al^{11,181}; see online list of references for this chapter).

[†]The numbers presented are those for the admission component of the model (MPM II0). MPM II24 was developed using data for 15,925 patients from the same ICUs.

[‡]MPM II24 uses only 13 variables.

APACHE, Acute Physiology and Chronic Health Evaluation; ICUs, intensive care units; MPM, Mortality Probability Model; SAPS, Simplified Acute Physiology Score.

APACHE system, the APACHE II, was published in 1985 by the same authors of the original model.¹⁰ This system introduced the prediction of mortality risk, providing a major reason for ICU admission from a list comprising 50 operative and nonoperative diagnoses. The MPM,²² developed by Stanley Lemeshow, provided additional contributions for the prediction of prognosis, using logistic regression techniques. Further developments in this field include the third version of the APACHE system (APACHE III)¹² and the second versions of the SAPS (SAPS II)¹³ and MPM (MPM II).¹⁴ All of them use multiple logistic regression to select and weight the variables and are able to compute the probability of hospital mortality risk for groups of critically ill patients. It has been demonstrated that they perform better than their old counterparts,^{23,24} and they represented the state of the art in this field by the end of the last century.

Since the early 1990s, owing to the progressive lack of calibration of these models, the performance of these instruments began to slowly deteriorate with the passage of time. Differences in the baseline characteristics of the admitted patients, in the circumstances of the ICU admission, and in the availability of general and specific therapeutic measures introduced an increasing gap between actual mortality rate and predicted mortality risk.²⁵ Overall, in the last years of the century, there was an increase in the mean age of the admitted patients, a larger number of chronically sick patients and immunosuppressed patients, and an increase in the number of ICU admissions due to sepsis.^{26,27} Although most of the models kept an acceptable discrimination, their calibration (or prognostic accuracy) deteriorated to such a point that major changes were needed.

An inappropriate use of these instruments outside their sampling space was responsible also for some misapplication of the instruments, especially for risk adjustment in clinical trials.²⁸⁻³⁰

In the early 2000s, several attempts were made to improve the old models. However, a new generation of general outcome prediction models was built that included models such as the MPM III developed in the IMPACT database in the United States,³¹ new models based on computerized analysis by hierarchical regression developed by some of the authors of the APACHE systems,³² the APACHE IV,³³ and the SAPS 3 admission model, developed by hierarchical regression in a worldwide database.^{34,35} Models based on other statistical techniques such as artificial neural networks and genetic algorithms have been proposed but, besides academic use, they never became used widely.^{36,37} These approaches have been revised more than once,³⁸ and will be summarized later.

RECALIBRATING AND EXPANDING EXISTING MODELS

All the existing general outcome prediction models used logistic regression equations to estimate the probabilities of a given outcome in a patient with a certain set of predictive variables. Consequently, the first approach to improve the calibration of a model when the original model is not able to adequately describe the population is to customize the model.³⁹ Several methods and suggestions have been proposed for this exercise,⁴⁰ based usually on one of two strategies:

- First-level customization, or the customization of the logit, developing a new equation relaying the score to the probability, such as one proposed by Le Gall or Apolone.^{41,42}
- Second-level customization, or the customization of the coefficients of the variables in the model as described for the MPM II₀ model,³⁹ which can be made either by keeping unchanged the relative weight of the variables in the model or eventually by changing also these weights (this latter technique involves the limit of second-level customization: from this point forward, so the researcher is developing a new model and not customizing an existing one). Usually the researcher customizing an existing model assumes that the relative weight of the variables in the model is constant.

Both of these methods have been used in the past with a partial success in increasing the prognostic ability of the models.^{39,43} However, both fail when the problem of the score is on discrimination or in its poor performance in subgroups of patients (poor uniformity of fit).⁴⁴ This fact can be justified by the lack of additional variables, more predictive in this specific context. The addition of new variables to an existing model has been done before^{45,46} and can be an appropriate approach in some cases. It can lead to very complex models, needs the collection of special data, and is also more expensive and time-consuming. The best tradeoff between the burden of data collection and accuracy should be tailored case by case. It should be noted that the aim of first-level customization, which is nothing more than a mathematical translation of the original logit in order to get a different probability of mortality risk, is to improve the calibration of a model and not to improve discrimination. It should therefore not be considered when the improvement of this parameter is considered important.

A third level of customization can be imagined, through the introduction in the model of new prognostic variables and the recomputation of the weights and coefficients for all variables, but—as mentioned before—this technique crosses the borders of customizing a model versus building a new predictive model. In past years, all these approaches have been tried.⁴⁷⁻⁴⁹

BUILDING NEW MODELS

Three general outcome prediction models have been developed and finally published: the SAPS 3 admission model in 2005, the APACHE IV in 2006, and the MPM III in 2007.⁵⁰

THE SAPS 3 ADMISSION MODEL

Developed by Rui Moreno, Philipp Metnitz, Eduardo Almeida, and Jean-Roger Le Gall on behalf of the SAPS 3 Outcomes Research Group, the SAPS 3 model was published in 2005.^{34,35} The study used a total of 19,577 patients consecutively admitted to 307 ICUs all over the world from 14 October to 15 December 2002. This high-quality multinational database was built to reflect the heterogeneity of current ICU case mix and typology all over the world, trying not to focus only on Western Europe and the United States. Consequently, the SAPS 3 database better reflects important differences in patients' and health care systems' baseline characteristics that are known to affect outcome. These

include, for example, different genetic makeups, different styles of living, and a heterogeneous distribution of major diseases within different regions, as well as issues such as access to the health care system in general and to intensive care in particular, or differences in availability and use of major diagnostic and therapeutic measures within the ICUs. Although the integration of ICUs outside Europe and the United States surely increased its representativeness, it must be acknowledged that the extent to which the SAPS 3 database reflects case mix on ICUs worldwide cannot be determined yet.

Based on data collected at ICU admission (± 1 hour), the authors developed regression coefficients by using multi-level logistic regression to estimate the probability of hospital death. The final model, which comprises 20 variables, exhibited good discrimination without major differences across patient typologies; calibration was also satisfactory. Customized equations for major areas of the world were computed and demonstrate a good overall goodness of fit. It is interesting that the determinant of hospital mortality probability changed remarkably from the early 1990s,¹² with chronic health status and circumstances of ICU admission now being responsible for almost three fourths of the prognostic power of the model.

To allow all interested parties to see the calculation of SAPS 3, completely free of charge, extensive electronic supplementary material (<http://dx.doi.org/10.1007/s00134-005-2762-6> and <http://dx.doi.org/10.1007/s00134-005-2763-5>, both accessed 30/06/2013) was published together with the study reports, including the complete and detailed description of all variables as well as additional information about SAPS 3 performance. Moreover, the SORG provides at the project website (www.saps3.org) several additional resources: First, a Microsoft Excel sheet is available and can be used to calculate a SAPS 3 “on the fly.” Second, a small Microsoft Access database allows for the calculation, storage, and export of SAPS 3 data elements.

However, as all outcome prediction models, SAPS 3 is slowly losing calibration, as recently demonstrated by several groups.⁵¹⁻⁵⁵ It seems to keep a good level of reliability and discrimination, but a recalibration process, which can be relatively easy to perform, must be done in the following years.

THE APACHE IV MODEL

In early 2006, Jack E. Zimmerman, one of the original authors of the original APACHE models, published in collaboration with colleagues from Cerner Corporation (Vienna, VA) the APACHE IV model.³³ The study was based on a database of 110,558 consecutive admissions during 2002 and 2003 to 104 ICUs in 45 U.S. hospitals participating in the APACHE III database. The APACHE IV model uses the worst values during the first 24 hours in the ICU and a multivariate logistic regression procedure to estimate the probability of hospital death.

Predictor variables were similar to those in APACHE III, but new variables were added and different statistical modeling has been used. The accuracy of APACHE IV predictions was analyzed in the overall database and in major patient subgroups. APACHE IV had good discrimination and calibration. For 90% of 116 ICU admission diagnoses, the ratio of observed to predicted mortality was not significantly

different from 1.0. Predictions were compared with the APACHE III versions developed 7 and 14 years previously: there was little change in discrimination, but aggregate mortality risk was systematically overestimated as model age increased. When examined across disease, predictive accuracy was maintained for some diagnoses but for others seemed to reflect changes in practice or therapy. A predictive model for risk-adjusted ICU length of stay was also published by the same group.⁵⁶ More information about the model and the possibility to compute the probability of death for individual patients is available at the website of Cerner Corporation (www.criticaloutcomes.cerner.com).

THE MPM₀ III MODEL

The MPM₀ III was published by Tom Higgins and associates in 2007.⁵⁰ It was developed using data from ICUs in the United States participating in the project IMPACT but there is almost no published data to evaluate its behavior outside the development cohort. As for the previous MPM models, the MPM₀ III does not allow the computation of a score but estimates directly the probability of death in the hospital.

DEVELOPING PREDICTIVE MODELS

SELECTING THE TARGET POPULATION

Although named “general,” most of the existing models are not applicable to all ICU patients. Patients with burns, admitted with coronary ischemia (or to rule out myocardial infarction), who were young (less than 16 or 18 years of age), in the postoperative phase of cardiac surgery, or with a very short length of ICU stay were explicitly excluded from the development of the majority of systems. This limitation is especially important when we evaluate specialized ICUs, with a particular case mix, but can also be important in general ICUs. In many cases, the application of exclusion criteria can imply the analysis of just a small proportion of the admitted patients, resulting in significant errors.

OUTCOME SELECTION

Outcome selection identifies the end point of interest, and at a minimum, the selected outcome should be as follows:

- A relatively common event
- Easily defined, recognized, and measured
- Clinically relevant
- Independent of therapeutic decisions

Fatality meets all the preceding criteria; however, there are confounding factors to be considered when using death as an outcome. The location of the patient at the time of death can considerably reduce hospital mortality rates. For example, in a study of 116,340 ICU patients, a significant decline in the ratio of observed and predicted death was attributed to a decrease in hospital mortality rate as a result of earlier discharge of patients with a high severity of illness to skilled nursing facilities.⁵⁷ In the APACHE III study, a significant regional difference in mortality rate was entirely

secondary to variations in hospital length of stay.⁵⁸ Improvements in therapy, such as the use of thrombolysis in myocardial infarction or steroids in *Pneumocystis* pneumonia and the acquired immunodeficiency syndrome⁵⁹ can dramatically reduce hospital mortality rate. Increases in the use of advance directives, do-not-resuscitate orders, and limitation or withdrawal of therapy all increase hospital mortality rates.

Variations in any of the previous factors will lead to differences between observed and predicted deaths that have little to do with case mix or effectiveness of therapy. Predictive instruments directed at long-term mortality predictions provide accurate prognostic estimates within the first month of hospital discharge, but their accuracy falls off considerably thereafter, because other factors, such as HIV infection or malignancy, dominate the long-term survival pattern.⁴⁵ Owing to these caveats, fatality is the most useful outcome for designing general severity of illness scores and predictive instruments.

Other outcome measures represent important issues in improving ICU care. These issues include the following:

- Morbidity and complication rates
- Organ dysfunction
- Resource use
- Duration of mechanical ventilation, use of pulmonary artery catheters
- Quality of life after ICU/hospital discharge
- Length of stay in the ICU

Case-mix adjustment is indispensable for studying morbidity, resource utilization, and length of stay. Although these outcomes are difficult to define and are sensitive to local conditions, they are related to the cost of care and have therefore been useful in measuring and comparing ICU efficiency.

All current outcome prediction models aim at predicting vital status at hospital discharge. It is thus incorrect to use them to predict other outcomes, such as the vital status at ICU discharge. This approach will result in a gross underestimation of mortality rates.⁶⁰

DATA COLLECTION

The next step in the development of a general outcome prediction model is the evaluation, selection, and registration of the predictive variables. At this stage major attention should be given to the variable definitions as well as to the time frames for data collection.⁶¹⁻⁶³ Very frequently models have been applied incorrectly, the most common errors being related to the following:

- The definitions of the variables
- The time frames for the evaluation and registration of the data
- The frequency of measurement and registration of the variables
- The applied exclusion criteria
- Data handling before analysis

It should be noted that all existing models have been calibrated for nonautomated (i.e., manual) data collection. The use of electronic patient data management systems

(with high sampling rates) has been demonstrated to have a significant impact on the results:^{64,65} the higher the sampling rate, the more outliers will be found and thus scores will be higher. The evaluation of intra- and interobserver reliability should always be described and reported, together with the frequency of missing values.

SELECTION OF VARIABLES

The number of variables used in severity and prognostic systems is influenced by the data collection burden, statistical considerations, measurement reliability, and frequency. Variable selection reflects a balance between adding variables with a diminishing impact on outcome and limiting variables to the strongest predictors to ease data collection and minimize processing errors. Variables should have these characteristics:

- Readily available and clinically relevant
- Plausible relationship to outcome and easily defined and measured
- Independent of treatment processes
- Verifiable by checks of data accuracy

Initial selection of variables can be either deductive (subjective), using terms that are known or suspected to influence outcome, or inductive (objective) using any deviation from homeostasis or normal health status. The deductive approach employs a group of experts, who supply a consensus regarding the measurements and events most strongly associated with the outcome. This approach is faster and requires less computational work; APACHE I and SAPS I both started this way. A purely inductive strategy, used by MPM, begins with the database, and tests candidate variables with a plausible relationship to outcome. In the SAPS 3 model several complementary methods have been used, such as logistic regression on mutually exclusive categories built using smoothed curves based on LOWESS (locally weighted scatterplot smoothing),⁶⁶ and multiple additive regression trees (MART).⁶⁷

As a practical matter, neither technique is used exclusively; all systems now use a combination of these techniques. Variables that have been used in severity and prognostic systems include the following:

- Age
- Chronic disease status or comorbid conditions
- Circumstances of ICU admission
- Physiologic measures
- Reasons for ICU admission and admitting diagnoses
- Cardiopulmonary resuscitation (CPR), mechanical ventilation prior to ICU admission
- Location and length of stay before admission
- Emergency surgery and operative status

Predictor variables should be easily defined and reliably measured to ensure uniform data collection and minimize scoring variations. For statistical purposes, variables are considered dichotomous (e.g., surgery or not), categoric (e.g., disease classification or patient location before admission), or continuous (blood pressure or heart rate). With very large sample sizes, some continuous variables may be

rendered dichotomous or categorical if it is discovered that there are strong and biologically sound threshold values beyond which their numerical value has no additional significance.

Weights for ICU admission diagnosis or reason for ICU admission (e.g., asthma vs. acute respiratory distress syndrome) significantly augment prognostic accuracy because a similar extent of physiologic derangement reflects substantial variations in mortality risk for different diseases. Interestingly, the circumstance of ICU admission such as the planned or unplanned character of the admission has been demonstrated to be very important. Systems that include weights for admitting diagnosis must have sufficient numbers of patients in each disease category to perform statistical analyses. Predictive instruments that ignore admitting diagnosis reduce the data collection burden, but perform poorly in ICUs with a case mix that differs significantly from the development database.

Location and length of stay before ICU admission account, at least partly, for lead-time bias, which has an important impact on outcome. For example, a patient treated for 2 days and then admitted to the ICU is at greater risk of death than a patient with the same diagnosis and severity of illness admitted from the emergency department.

The accuracy of any scoring system depends on the quality of the database from which it was developed. Even with well-defined variables, significant interobserver variability is reported.^{68,69}

In calculating the scores, several practical issues should be discussed.^{70,71} First, exactly which value for any parameter should be considered? It is true that for many of the more simple variables, several measurements will be taken during any 24-hour period. Should the lowest, highest, or an average be taken as the representative value of that day? There is a general consensus that, for the purposes of the score, the worst value in any 24-hour period should be considered. Second, what about missing values? Should the last known value repeatedly be considered as representative until a new value is obtained, or should the mean value between two successive values be taken? Both options make assumptions that may influence the reliability of the score. The first option assumes that we have no knowledge of the evolution of values with time and the second assumes that changes are usually fairly predictable and regular. However, we prefer this second option because values may be missing for several days and repeating the last known value may involve considerable errors in calculation. In addition, changes in most of the variables measured (platelet count, bilirubin, urea) are, in fact, usually fairly regular, moving up or down in a systematic manner.

VALIDATION OF THE MODEL

All predictive models developed for outcome prediction need, of course, to be validated, that is, to demonstrate their ability to predict the outcome under evaluation. Three aspects should be evaluated in this context: the first aspect is the calibration, or the degree of correspondence between the predictions of the model and observed results. The second is discrimination, or the capability of the model to distinguish observations with a positive outcome from those

with a negative outcome. The third is the uniformity of fit of the model, which is related to the performance over various subgroups of patients.

The evaluation of the calibration and discrimination has been named *goodness of fit*. The evaluation of the performance of the model in major subgroups has been named *uniformity of fit*.

GOODNESS OF FIT

The evaluation of the goodness of fit comprises the evaluation of calibration and discrimination in the analyzed population. Calibration evaluates the degree of correspondence between the estimated probabilities of fatality and the actual fatality in the analyzed sample. Several methods are usually proposed: observed/estimated (O/E) mortality ratios, Flora's Z score,⁷² Hosmer-Lemeshow goodness of fit tests,⁷³⁻⁷⁵ and Cox calibration regression and calibration curves.

O/E mortality ratios are computed by dividing the observed fatality (in other words, the number of deaths) by the predicted fatality (in other words, the sum of the probabilities of death of all patients in the sample). In a perfectly calibrated model this value should be 1.

Hosmer-Lemeshow goodness of fit tests are two chi-square statistics proposed for the formal evaluation of the calibration of predictive models.⁷³⁻⁷⁵ In the \hat{H} test, patients are classified into 10 groups according to their probabilities of death. Then, a chi-square statistic is used to compare the observed number of deaths and the predicted number of survivors with the observed number of deaths and the observed number of survivors in each of the groups. The formula is (Equation 1):

$$\hat{C}_g = \hat{H}_g = \sum_{l=1}^g \frac{(o_l - e_l)^2}{e_l(1 - \bar{\pi}_l)}$$

with g being the number of groups (usually 10), o the number of events observed in group l , e the number of events expected in the same group, and $\bar{\pi}_l$ the mean estimated probability, always in group l . The resulting statistic is then compared with a chi-square table with 8 degrees of freedom (model development) or 10 degrees of freedom (model validation), in order to know if the observed differences can be explained exclusively by random fluctuation. The Hosmer-Lemeshow \hat{C} test is similar, with the 10 groups containing an equal number of patients. Hosmer and Lemeshow demonstrated that the grouping method used on the \hat{C} statistics behaves better when most of the probabilities are low.⁷³

These tests are nowadays considered to be mandatory for the evaluation of calibration,⁷⁶ although they are subject to criticism.^{77,78} It should be stressed that the analyzed sample must be large enough to have the power to detect the lack of agreement between predicted and observed mortality rates.⁴⁰

The Hosmer-Lemeshow tests are very sensitive to the size of the sample. When the sample is small, the test is usually underpowered to detect poor fit; when the sample size is very large, even minor, insignificant differences between the predicted and the observed fatality will result in a significant chi-square; for this reason, more and more investigators, especially those dealing with large databases, prefer to use the Cox calibration regression, in which the relation between

the expected and the observed probabilities is assessed by logistic regression with hospital death being the dependent variable and the natural logarithm of the odds of the probabilities given by the model being the independent variable. If the intercept is 0 and the slope of the model 1, then the calibration is perfect.⁴⁹

This is the one of the best methods to provide the user with a quantitative measure of calibration, but it does not indicate fully the deviations between observed and predicted mortality rates, in particular in the direction, extent, and risk classes affected by these deviations. This last information is more or less provided by the traditional calibration plot, which, however, is not a real curve (single points are theoretically independent from each other), is not a formal statistical method, and consequently does not provide the uncertainty of the estimate. Another weak point of the most commonly used calibration assessment methods (i.e., the Hosmer–Lemeshow statistics combined with the traditional calibration plot) is that they average the risk of patients in each decile, thus not using the entire information carried by each patient. These shortcomings were recently addressed by a new statistical approach, the GiViTI calibration belt,⁵³ recently used by Poole and colleagues in the comparison of the calibration of SAPS II and 3.⁵³ However, it is also not perfect, because most of the time there is a left (low-risk) deviation of the distribution of risks and the test becomes less helpful and informative. Calibration curves are also used to describe the calibration of a predictive model. These types of graphics compare observed and predicted mortality risks. They can be misleading, because the number of patients usually decreases from left to right (when we move from low probabilities to high probabilities), and as a consequence, even small differences in high-severity groups appear visually more important than small differences in low-probability groups. It should be stressed that calibration curves are not a formal statistical test.

Discrimination evaluates the capability of the model to distinguish between patients who die from patients who survive. This evaluation can be made using a nonparametric test such as Harrell's C index, using the order of magnitude of the error.⁷⁹ This index measures the probability of, for any two patients chosen randomly, the one with the greater probability to have the outcome of interest (to be dead). It has been shown that this index is directly related with the area under the receiver operating characteristic (ROC) curve and that it can be obtained as the parameter of the Mann-Whitney-Wilcoxon statistic.⁸⁰ Additional computations can be used to compute the confidence interval of this measure.⁸¹

The concept of the area under the ROC curve is derived from psychophysical tests. In an ROC curve, a series of two by two contingency tables are built, varying from the smallest to the largest score value. For each table the rate of true-positive (or sensitivity) and the false-positive rate (or 1 minus the specificity) are calculated. The final plot of all possible pairs of rates of true-positives versus false-positives gives then the visual representation of the ROC curve.

The interpretation of the area under the ROC curve is easy: a virtual model with a perfect discrimination would have an area of 1.0, a model with a discrimination no better than chance has an area of 0.5. Discriminative abilities are

said to be satisfactory when the ROC curve is greater than 0.70. General outcome prediction models usually have areas greater than 0.80. Several methods have been described to compare the areas under two (or more) ROC curves,⁸²⁻⁸⁴ but they can be misleading if the shape of the curves is different.⁸⁵

Other measures have been utilized, based on classification tables, with describing sensitivity, specificity, positive and negative predictive values, and the correct classification rates. However because these calculations must use a fixed cutoff (usually 10%, 50%, or 90%), their value is limited.

The relative importance of calibration and discrimination depends on the intended use of the model. Some authors advise that for group comparison calibration is especially important⁸⁶ and that for decisions involving individual patients both parameters are important.⁸⁷

UNIFORMITY OF FIT

The evaluation of calibration and discrimination in the analyzed sample is nowadays current practice. More complex is the identification of subgroups of patients when the behavior of the model is nonoptimal. These subgroups can be viewed as influential observations in model building and their contribution for the global error of the model can be vary large.⁸⁸

The most important subgroups are related to the case-mix characteristics that can be eventually related to the outcome of interest:

- The intrahospital location before ICU admission
- The surgical status
- The degree of physiologic reserve (age, comorbid conditions)
- The acute diagnosis (including the presence, site, and extension of infection at ICU admission)

Although some authors such as Rowan and Goldhill in the United Kingdom^{89,90} and Apolone and Sicignano in Italy^{42,91} have suggested that the behavior of a model can depend to a significant extent on the case mix of the sample, no consensus exists about the subpopulations that should mandatorily be analyzed.⁴⁴

UPDATING SEVERITY SCORES

Changes in the characteristics of the populations, changes in the therapy of major diseases, and the introduction of new diagnostic methods all imply modifications that result in necessary updates. Moreover, the use of a model outside its development population can eventually imply its modification and adaptation.

USING A SEVERITY OF ILLNESS SCORE

CALCULATING A SEVERITY OF ILLNESS SCORE

Using the original score sheets (or a computer software, well developed and validated), a score is assigned to each variable, depending on its deviation from normal values. The arithmetic sum of these variable scores (the sum score) represents the severity score for that patient, which is then used in the equation to predict hospital death. As described earlier, this approach was not chosen by any of the MPM

systems, in which the variables are directly used to compute a probability of death in the hospital by a logistic regression equation.

TRANSFORMING THE SCORE INTO A PROBABILITY OF DEATH

The transformation of the severity score into a probability of death in the hospital uses a logistic regression equation. The dependent variable (hospital mortality) y is related to the set of independent (predictive) variables by the equation:

$$y = b_0 + b_1x_1 + b_2x_2 \dots b_kx_k$$

with b_0 being the intercept of the model, x_1 to x_k the predictive variables and b_1 to b_k the estimated regression coefficients. The probability of death is then given by:

$$\text{Probability of death} = \frac{e^{\text{logit}}}{1 + e^{\text{logit}}}$$

with the logit being y as described before. The logistic transformation included in this equation allows the S-shaped relationship between the two variables to become linear (on the logit scale). In the extremes of the score (very low or very high values) changes in the probability of death are small; for intermediate values, even small changes in the score are associated with very large changes in the probability of death. This ensures that outliers do not influence the prediction too much.

APPLICATION OF A SEVERITY OF ILLNESS SCORE: EVALUATION OF PATIENTS

All existing models aim at predicting an outcome (vital status at hospital discharge) based on a given set of variables: they estimate the outcome of a patient with a certain clinical condition (defined by the registered variables), treated in a hypothetical reference ICU. Several issues, however, need to be taken into account in order to apply one of the previously described models in another population:

- Patient selection
- Evaluation and registration of the predictive variables
- Evaluation and registration of the outcome
- Computation of the severity score
- Transformation of the score in a probability of death

After validation, the utility and applicability of a model must be evaluated. Literature is full of models developed in large populations that failed, when applied within other contexts.^{42,43,89,92-96} Thus, this question can only be answered by validating the model in its final population. The potential applications of a model—and consequently its utility—are different for individual patients and for groups.⁹⁷

EVALUATING INDIVIDUAL PATIENTS

Some evidence exists that suggests that statistical methods behave better than clinicians in predicting outcome,⁹⁸⁻¹⁰⁵ or that they can help clinicians in the decision-making process.¹⁰⁶⁻¹⁰⁸ This opinion is, however, controversial,¹⁰⁹⁻¹¹¹ especially for decisions to withdraw or to withhold therapy.¹¹² Moreover, the application of different models to the same

patient results frequently in very different predictions.¹¹³ Thus, application of these models to individual patients for decision making is not recommended.¹¹⁴

It should not be forgotten that such statistical models are of a probabilistic nature. A well-calibrated model, applied to an individual patient may, for example, predict a hospital mortality rate of 46% for this individual; this, however, just means that for a group of 100 patients with a similar severity of illness, 46 patients are predicted to die; it makes no statement if the individual patient is included in the 46% who will eventually die or in the 54% who will eventually survive.

It should be noted that severity scores have been proposed for applications as diverse as to determine the use of total parenteral nutrition¹¹⁵ or the identification of futility in intensive care medicine.¹¹⁶ Some authors demonstrated that knowledge of predictive information will not have an adverse effect on the quality of care, helping at the same time to decrease the consumption of resources and to increase the availability of beds.¹¹⁷

One field in which the scientific community agrees consensually is the stratification of patients for inclusion into clinical trials and for the comparison of the balance of randomization to different groups.¹¹⁸

EVALUATING GROUPS OF PATIENTS

At a group level, general outcome prediction models have been proposed for two objectives: distribution of resources and performance evaluation. Several studies were published describing methods used to identify and to characterize patients with a low risk of death.¹¹⁹⁻¹²³ This type of patient, who requires only basic monitoring and general care, could eventually be transferred to other areas of the hospital.^{108,124} One could, however, also argue that these patients have a low mortality risk only because they have been monitored and cared for in an ICU.¹²⁵ Also, the use of current instruments is not recommended as a triage instrument in the emergency department,¹²⁶ and also the use of early physiologic indicators outside the ICU is being questioned.¹²⁷

Moreover, patient costs in the ICU depend on the amount of required (and utilized) nursing workload use. Patient characteristics (diagnosis, degree of physiologic dysfunction) are thus not the only determinants: costs depend also on the practices and policies in a given ICU. To focus our attention on the effective use of nursing workload¹²⁸ or the dynamic evolution of the patient^{129,130} seems thus a more promising strategy than those approaches based exclusively on the condition of the patients during the first hours in the ICU or in the O/E length of stay in the ICU.^{58,131,132}

On the other hand, general outcome prediction models have been proposed to identify patients who require more resources.¹³³ Unfortunately, these patients only rarely can be identified at ICU admission, because their degree of physiologic dysfunction during the first 24 hours in the ICU tends usually to be moderate, although very variable.¹³⁴⁻¹³⁶ And even if some day these patients might be well identified, the question of what to do with this information remains.

Another important area in which these type of models have been used is evaluation of ICU performance. Several investigators proposed the use of standardized mortality ratios (SMR) for performance evaluation,

assuming that current models can take into account the main determinants of mortality risk.¹³⁷ The SMR is computed by dividing the observed mortality rate by the averaged predicted mortality rate (the sum of the individual probabilities of death of all the patients in the sample). Additional computations can be made to estimate the confidence interval of this ratio.¹³⁸

The interpretation of the SMR is easy: a ratio lower than 1 implies a performance better than the reference population and a ratio greater than 1 indicates a performance worse than the reference population. This methodology has been used for international comparison of ICUs,* comparison of hospitals,[†] ICU evaluation,¹⁴³⁻¹⁴⁶ management evaluation,^{142,147,148} and the influence of organization and management factors on the performance of the ICU.¹⁴⁹

Before applying this methodology, six questions should always be answered:

1. Can we evaluate and register all the data needed for the computation of the models?
2. Can the models be used in the large majority of our patients?
3. Are existent models able to control for the main patient characteristics related to mortality?
4. Has the reference population been well chosen and are the models well calibrated to this population?
5. Is the sample size large enough to draw meaningful differences?
6. Is vital status at ICU discharge the main performance indicator?

Each of these assumptions has been questioned in past years and there is no definitive answer at this time. However, most investigators believe that performance is multidimensional and consequently that it should be evaluated in several dimensions.^{25,150} The problem of sample size seems especially important with respect to the risk of a type II error (in other words, to say that there are no differences when they exist).

Moreover, the comparison between observed and predicted might make more sense if done separately in low-, intermediate-, and high-risk patients, because the performance of an ICU can change according to the severity of the admitted patients. This approach was advocated in the past based on theoretical concerns,¹⁵¹⁻¹⁵³ but was used only in a small number of studies.^{149,154} Multilevel modeling with varying slopes can be an answer for the developers of such models.^{25,155}

ORGAN DYSFUNCTION/FAILURE SCORING SYSTEMS

Organ failure scores are designed to describe organ dysfunction/failure more than to predict survival. In the development of organ function scores, three important principles need to be remembered.¹⁷ First, organ failure is not a simple all-or-nothing phenomenon; rather, a spectrum or continuum of organ dysfunction exists from very mild

altered function to total organ failure. Second, organ failure is not a static process and the degree of dysfunction may vary with time during the course of disease so that scores need to be calculated repeatedly. Third, the variables chosen to evaluate each organ need to be objective, simple, and available but reliable, routinely measured in every institution, specific to the organ in question, and independent of patient variables, so that the score can be easily calculated for any patient in any ICU. Interobserver variability in scoring can be a problem with more complex systems^{63,156} and the use of simple, unequivocal variables can avoid this potential problem. Ideally, scores should be independent of therapeutic variables, as stressed by Marshall and coworkers,¹⁵ but in fact, this is virtually impossible to achieve as all factors are more or less treatment dependent. For example, the PaO₂/Fio₂ ratio is dependent on ventilatory conditions and positive end-expiratory pressure (PEEP), platelet count may be influenced by platelet transfusions, urea levels are affected by hemofiltration, and so on.

The process of organ function description is relatively new and there is no general agreement on which organs to assess and which parameters to use. Many different scoring systems have been developed for assessing organ dysfunction,^{15-17,157-165} differing in the organ systems included in the score, the definitions used for organ dysfunction, and the grading scale used.^{71,166} The majority of scores include six key organ systems—cardiovascular, respiratory, hematologic, central nervous, renal, and hepatic—with other systems, such as the gastrointestinal system, less commonly included. Early scoring systems assessed organ failure as either present or absent, but this approach is very dependent on where the limits for organ function are set, and newer scores consider organ failure as a spectrum of dysfunction. Most scores have been developed in the general ICU population, but some were aimed specifically at the septic patient.^{17,158,159,163,164} Three of the more recently developed systems will be discussed later, the main difference between them being in their definition of cardiovascular system dysfunction (Table 73.2).

MULTIPLE ORGAN DYSFUNCTION SCORE

This scoring system was developed by a literature review of clinical studies of multiple organ failure from 1969 to 1993.¹⁵ Optimal descriptors of organ dysfunction were thus identified and validated against a clinical database. Six organ systems were chosen, and a score of 0 to 4 allotted for each organ according to function (0 being normal function through 4 for most severe dysfunction) with a maximum score of 24. The worst score for each organ system in each 24-hour period is taken for calculation of the aggregate score. A high initial Multiple Organ Dysfunction Score (MODS) correlated with ICU mortality risk and the delta MODS (calculated as the MODS over the whole ICU stay less the admission MODS) was even more predictive of outcome.¹⁵ In a study of 368 critically ill patients the MODS was found to better describe outcome groups than the APACHE II or the organ failure score, although the predicted risk of mortality was similar for all scoring systems.¹⁶⁷ The MODS has been used to assess organ dysfunction in clinical studies of various groups of critically ill patients, including those with severe sepsis.¹⁶⁸⁻¹⁷¹

GCS, Glasgow Coma Scale; HR, heart rate; LOD, Logistic Organ Dysfunction; MAP, mean arterial pressure; MODS, Multiple Organ Dysfunction Score; SAPS, Simplified Acute Physiology Score; SOFA, Sequential Organ Failure Assessment; WBC, white blood cells.

SEQUENTIAL ORGAN FAILURE ASSESSMENT SCORE

The sequential organ failure assessment (SOFA) score was developed in 1994 during a consensus conference organized by the European Society of Intensive Care and Emergency Medicine in an attempt to provide a means of quantitatively and objectively describing the degree of organ failure over time in individual, and groups of, septic patients.¹⁷ Initially termed the *sepsis-related organ failure assessment score*, the score was then renamed the *sequential organ failure assessment* because it was realized that it could be applied equally to nonseptic patients. In devising the score, the participants of the conference decided to limit to six the number of systems studied: respiratory, coagulation, hepatic, cardiovascular, central nervous system, renal. A score of 0 is given for normal function through 4 for most abnormal, and the worst values on each day are recorded. Individual organ function can thus be assessed and monitored over time, and an overall global score can also be calculated. A high total SOFA score (SOFA max) and a high delta SOFA (the total maximum SOFA minus the admission total SOFA) have been shown to be related to a worse outcome,^{129,172} and the total score has been shown to increase over time in nonsurvivors compared to survivors.¹⁷² The SOFA score has been used for organ failure assessment in several clinical trials, including one in septic shock patients.¹⁷³⁻¹⁷⁶

LOGISTIC ORGAN DYSFUNCTION SYSTEM SCORE

This score was developed in 1996 using multiple logistic regression applied to selected variables from a large database of ICU patients.¹⁶ To calculate the score, each organ system receives points according to the worst value for any variable for that system on that day. If no organ dysfunction is present, the score is 0, rising to a maximum of 5. As the

relative severity of organ dysfunction differs between organ systems, the Logistic Organ Dysfunction System (LODS) score allows for the maximum of 5 points to be awarded only to the neurologic, renal, and cardiovascular systems. For maximum dysfunction of the pulmonary and coagulation systems, a maximum of 3 points can be given for the most severe levels of dysfunction; and for the liver, the most severe dysfunction receives only 1 point. Thus, the total maximum score is 22. The LODS score is designed to be used as a once-only measure of organ dysfunction in the first 24 hours of ICU admission, rather than as a repeated assessment measure. The LODS system is quite complex and seldom used; nevertheless, it has been used to assess organ dysfunction in clinical studies.¹⁷⁷

COMPARISON OF THE DESCRIBED SYSTEMS

The main difference among the three described models is the method chosen for the evaluation of the cardiovascular dysfunction: SOFA uses blood pressure and the level of adrenergic support, MODS uses a composed variable (heart rate \times ratio of central venous pressure) and mean arterial pressure (heart rate \times central venous pressure/mean arterial pressure), and LOD score uses the heart rate and the systolic blood pressure. There are now a few comparisons among them, not describing clinically significant differences.

Mixed models, integrating organ failure assessment scores, and general severity scores have been published,^{162,178} but they never gained widespread acceptance.

SCORING SYSTEMS FOR SPECIFIC CLINICAL CONDITIONS

Several scoring systems have been developed to be applied on a subsample of patients with specific clinical conditions,

such as for cardiac surgery, severe sepsis and septic shock, trauma, and acute renal failure. These systems, given their specificity and limited applicability, will not be covered here, but the reader should realize that they can be extremely helpful when dealing with patients with trauma or in the postoperative stage of cardiac surgery.

DIRECTIONS FOR FURTHER RESEARCH

In the last year a new generation of general outcome prediction models has been developed. More complex than their old counterparts, relying heavily in computerized data registry and analysis (although the SAPS 3 model can be still computed by hand), incorporating more extensively the reasons and circumstances responsible or associated with ICU admission, these instruments must now be evaluated outside their development populations.

The choice between them remains largely subjective and depends on the reference database that the user wants to use: the U.S. centers participating in the APACHE III database or a more heterogeneous sample of ICUs across all major regions of the globe. The absence of any fee regarding the SAPS 3 model and the existence of equations specific for each region of the world should be weighted with the paid participation in a continuous database program, providing a more professional support and analysis of the data.

No matter the model chosen, users should keep in mind that the accuracy of these models is dynamic and should be periodically retested, and that when accuracy deteriorates these models must be revised and updated. Also, it is important to remember that these instruments have been developed to be used in populations of patients with critical illness and not in individual patients; consequently, their use in individual patients should always be complementary and not alternative to the use of clinical evaluation, because statistical predictive methods are prone to error, especially in the individual patient.^{179,180}

KEY POINTS

- Scoring systems have been broadly used in medicine for several decades, both for clinical research and for the evaluation of ICU effectiveness.
- The evaluation of severity of illness in the critically ill patient is made through the use of severity scores and (general) prognostic models. Severity scores are instruments that aim at stratifying patients based on their severity, assigning to each patient an increasing score as the severity of illness increases. General prognostic models, apart from their ability to stratify patients according to their severity, aim at predicting a certain outcome based on a given set of prognostic variables and a certain modeling equation.
- Several different systems are available to describe and classify ICU populations, to compare severity of illness, and to predict mortality risk in their patients. These systems perform well globally, but there are still

KEY POINTS (Continued)

concerns about errors in prediction caused by differences in patient selection, lead-time bias, sample size, representativeness of the databases used to develop the systems, and poor calibration within patient subgroups and across geographic locations.¹⁸²

- The most widely used general outcome prognostic systems for adults are the APACHE II, III, and IV; the SAPS II and 3; and the MPM II and III.
- At the patient level, severity scores and prognostic models have been used for purposes as diverse as determining the use of total parenteral nutrition, the identification of futility in intensive care medicine, the use of new therapies in sepsis, the stratification of patients for inclusion into clinical trials, and the analysis of the balance of randomization in different groups during clinical trials. At the group level, general outcome prediction models have been proposed for the allocation of resources and performance evaluation, through the use of the observed to expected mortality ratio or SMR.
- Organ failure scores are designed to describe in a repetitive way the presence and degree of organ dysfunction/failure in critically ill patients. Most of them evaluate six key organ systems (cardiovascular, respiratory, hematologic, central nervous, renal, and hepatic), with other systems, such as the gastrointestinal system, less commonly included. All of them use a combination of physiologic and therapeutic variables to access organ dysfunction/failure.
- Disease-specific scoring systems have been developed to be applied on more specific populations with specific clinical conditions, such as cardiac surgery or trauma. Models specifically developed to be used in neonates or children are also available.
- The choice between existing systems remains largely subjective and depends on the reference database that the user wants to use: the U.S. centers participating in the APACHE II or IV database or a more heterogeneous sample of ICUs across all major regions of the globe (as in SAPS 3). Complexity, cost, and the existence of equations specific for each region of the world should be weighted as well as the participation in a continuous database program, providing a more professional support and analysis of the data. No matter the model chosen, accuracy should be periodically retested and revised and updated as it deteriorates. The models should be complementary, and they should not be used as an alternative to clinical evaluation.

CHAPTER OUTLINE

TRAINING ASPIRATIONS FOR INTENSIVE CARE MEDICINE

THE TRAINING ENVIRONMENT

CURRENT TRAINING IN INTENSIVE CARE MEDICINE

COMPETENCY-BASED TRAINING

DEFINING CORE COMPETENCIES

EVOLVING PROFESSIONAL ROLES: IMPLICATIONS FOR TRAINING

PRACTICAL IMPLICATIONS OF COMPETENCY-BASED TRAINING

ASSESSMENT

DELIVERING TRAINING AND ASSESSMENT IN THE WORKPLACE: ROLE OF SIMULATION

SUMMARY

Training programs in intensive care medicine (ICM) vary worldwide in content, assessment, and duration, influenced heavily by domestic traditions and training structures. Even countries and health care communities that have much in common may differ significantly in curriculum content, delivery, assessment, accreditation, and requirements for continuing professional development, particularly when ICM exists as multiple subspecialties. In many countries the resources available to support training and education are inadequate, aggravated in the European context by legislation that requires workplace-based education to be delivered within the 48-hour weekly limit on working hours.

These challenges have acted as a stimulus to develop web-based methods of knowledge dissemination, workplace-based approaches to reflective learning, and e-portfolios for documentation of learning outcomes. Since 2003 there have been a number of successful initiatives to harmonize the outcomes of training through common competencies and the development of international standards for programs of training in ICM. Further work is needed to develop techniques of training and reliable methods of assessment, particularly in the domain of human factors and behavioral skills, framed by the ethos of life long learning as a device for improving the care that we offer to our patients and families.

TRAINING ASPIRATIONS FOR INTENSIVE CARE MEDICINE

The purpose of any medical education program should be to integrate knowledge, skills, attitudes, and behaviors within a sound ethical and professional framework that

encourages reflective life long learning, with the aim of producing competent and caring practitioners who possess both team-working and leadership capacities. Achieving this objective requires a firm focus on the needs of patients and confident and effective structures and processes for training and education. The American College of Critical Care Medicine states,¹ “Critical care medicine trainees and faculty must acquire and maintain the skills necessary to provide state-of-the art clinical care to critically ill patients, to improve patient outcomes, optimize intensive care unit utilization, and continue to advance the theory and practice of critical care medicine. This should be accomplished in an environment dedicated to compassionate and ethical care.” To this statement one could add: *using the knowledge and resources of a multiprofessional team and involvement of patients and caregivers.*

THE TRAINING ENVIRONMENT

Training and service are necessary companions. In the last 20 years, health systems worldwide have seen that patients’ expectations of safe and reliable health care are not always satisfied.^{2,3} It is reasonable for patients to expect that their care should be delivered by fully trained specialists and not by less experienced individuals or those in training grades. However, this expectation is made difficult to satisfy by cost pressures, rationing, increased throughput, staffing limitations, and reduced hours of work for trainees.^{4,5} These challenges are a particular problem for acute and emergency care, including critical care,⁶ but it is in precisely these areas that some of the most innovative solutions can be found.

Physician assistants or extended-role nurse practitioners are now active in many roles. In ICM, the United Kingdom

has developed a program for advanced critical care practitioners⁷ derived from the physicians' Competency-Based Training in Intensive Care Medicine (CoBaTrICE) program. Critical care and outreach, medical emergency teams,⁸ and the United Kingdom's hospital at night and 24/7 teams⁹ all involve senior nurses with diagnostic and management training. In the United States, growth of the hospitalist movement into a new specialty demonstrates how the clinical demands of acutely ill patients can have an impact on training and education.¹⁰ The National Organization of Nurse Practitioner Faculties has developed a national program of competencies that includes diagnostic algorithms and treatment based on protocols,¹¹ and many of the competencies are centered around management of acutely ill or physiologically unstable patients. Acutely ill patients are thus necessarily cared for by multiple teams involving physicians, nurses, and allied health care professionals. Such teams have rapidly changing membership, and colleagues often do not know each other well. Accurate and comprehensive clinical handoffs/handovers need to be standardized in order to ensure continuity of care. This care needs to be supplemented by objective processes that pick up measures of physiologic deterioration, escalate concerns in a timely and appropriate manner, and can call upon the best person at the right time, every time. Training to acquire these complex skills in the acute and emergency care environment must be embedded in undergraduate curricula for all health care professionals.^{12,13}

CURRENT TRAINING IN INTENSIVE CARE MEDICINE

The emergence of critical care medicine from the poliomyelitis epidemics of the 1950s was underpinned by developments in cardiorespiratory pathophysiology and organ system support led by anesthesiology and respiratory medicine. The safety record of anesthesiology combined with better technology and drugs has enabled increasingly complex surgery and has extended the role of the anesthetist into postoperative intensive care. Respiratory physicians also have a traditional association with critical care, particularly in the United States, where they remain the most numerous specialists within critical care medicine. Principles of ICM are a mandatory component of many specialty training programs worldwide, but the extent to which this training is recognized as specialist ICM training varies. Specialists from other primary disciplines such as surgery and internal and emergency medicine (and pediatrics) participate in critical care, but with varying degrees of access to, or inclusion of, competencies in ICM.

In a survey of 41 countries carried out by the CoBaTrICE Collaboration¹⁴ under the aegis of the European Society for Intensive Care Medicine (ESICM), 54 different ICM training programs were identified (37 within the European region) that ranged in duration from 3 months to 6 years (most frequently 2 years). Entry criteria were significantly different between some countries with regard to the structure and format of the training program. Nursing surveys demonstrate similar diversity in their training programs. The CoBaTrICE survey was updated for European Region countries in 2009,¹⁵ and demonstrated that although

progress had been made on convergence in specialty status and shared competencies there were still significant deficiencies in standards for assessment, quality assurance, and infrastructure support for training. Currently 10 European Region countries use the harmonized CoBaTrICE competencies.

Most countries observe one or more of the following models of ICM training: primary specialty (critical care training directly after medical school), subspecialty (critical care training as an exclusive component of a primary discipline), or supraspecialty training (a common critical care training shared by multiple primary specialties).

In *primary specialty* training, ICM is regarded as a fully independent specialty with a separate training program accessed directly from the undergraduate level or from a common stem at internship or residency. This training may be undertaken in addition to a complementary primary specialty, commonly anesthesiology or internal medicine.

Subspecialty refers to ICM training within a parent specialty and exclusive to it. In the majority of such systems, ICM training can be accessed only through anesthesiology. Other disciplines, such as internal medicine and surgery, may offer their own subspecialty training in ICM. These separate routes may be related to each other but are administered differently and often have different components. Certification will reflect the base specialty but often documents subspecialty status also.

Supraspecialty training is the most common model. Here, a primary specialty is chosen and intensive care training is grafted onto it, either in a modular or in a single-block format. Certification in ICM requires certification in the primary specialty also. It allows a number of specialties to access common ICM training. In practice, however, the specialties remain predominantly anesthesiology, internal medicine (adult and pediatric), and respiratory medicine. ICM is now a primary specialty in Spain, the United Kingdom, Switzerland, Australia, and New Zealand; all except Spain also offer dual certification in ICM and another primary specialty.

Outside the CoBaTrICE program and those countries that have adopted it, few national programs define the outcomes of training explicitly in terms of the competencies expected of a specialist in ICM. There is tacit acknowledgment that the terms "attending," "consultant," and "specialist" may have administrative and logistic equivalence within individual countries and that a "good" specialist in one country is likely to be as well equipped with knowledge and skills as a good specialist in another, but there is little evidence to prove this, whereas there is solid evidence that standards of assessment and quality assurance vary widely between countries and even between different specialty programs within countries.¹⁵

Specialist status in all these schemes is obtained through some combination of time spent in the program, competency-based assessments, case reports, submission of diploma theses, oral (*viva voce*) examination, and clinical examination. There does not as yet exist an enforced recertification process specifically for ICM in any country, nor is there an agreed-upon standard for benchmarking intensive care units or training programs against international peers, though such standards are now being developed.¹⁶ For example, the United Kingdom has now

established a multicollegiate Faculty of Intensive Care Medicine responsible for the new primary specialist training program in ICM, and for standards of revalidation and peer review.^{17,18}

COMPETENCY-BASED TRAINING

Competencies are a method for describing the knowledge, skills, attitudes, and behavior expected of specialists in terms of what they are able to do. Several national regulatory bodies for physicians have started to modify their training programs from syllabus-based, examination-driven systems to programs based on competencies assessed in the workplace, particularly the United Kingdom, Canada (using the CanMEDS framework¹⁹), and the United States. The challenge for trainers and trainees is to develop robust methods for workplace-based assessment and to create the necessary flexibility within training programs to allow time-based training to be replaced by programs in which trainees acquire competencies at different rates. This has been made more difficult by limitations on working hours.^{4,5} The resultant friction between service and training has led to poor use of assessment tools and an increasing belief that excellence in some has been sacrificed for a basic level of competence in many.²⁰

The CoBaTrICE Collaboration was formed in 2003 to harmonize standards of training in ICM internationally, first by defining outcomes of specialist ICM training and then by developing guidance and standards for assessment of competence and program infrastructure and quality assurance.^{21,22} The underlying principle of this initiative was the concept that an ICM specialist trained in one country should have the same core skills and abilities as one trained in another, thereby ensuring a common standard of clinical competence. This follows the European Union ethos of free movement of professionals and mutual recognition of medical qualifications between member states.²³ Competency-based training makes convergence possible by defining the outcomes of specialist training—a common “end product”—rather than enforcing rigid structures and processes of training. A minimum standard of knowledge, skills, attitudes, and behavior is defined a priori and applied to existing structures and processes of training; acquisition and assessment of competence occur during training in the workplace.

DEFINING CORE COMPETENCIES

The CoBaTrICE project has used consensus techniques—an extensive international consultation process using a modified online Delphi involving more than 500 clinicians in more than 50 countries, an eight-country postal survey of patients and relatives, and an expert nominal group—to define the core competencies required of a specialist in ICM.^{21,24} These competencies have been linked to a comprehensive syllabus, relevant educational resources, and guidance for the standardized assessment of competence in the workplace via a dedicated website.²² Since its launch in September 2006, 10 national training programs have adopted CoBaTrICE, and others have made use of the materials. In

2008, the second phase of the project developed international standards for national training programs in ICM,¹⁶ and further refined the methods of assessment of competence. The implementation and long-term evaluation of the CoBaTrICE program will be necessary to assess its impact on an individual's competence and harmonization of ICM training. In the United States, a multisociety initiative has used a similar methodology to the CoBaTrICE program to create common competencies.²⁵

EVOLVING PROFESSIONAL ROLES: IMPLICATIONS FOR TRAINING

The CoBaTrICE Delphi demonstrated the importance that intensive care clinicians attach not only to the acquisition of procedural technical skills but equally to aspects of professionalism—communication skills, attitudes and behavior, governance, team working, and judgment.²⁴ The intensivist is akin to an “acute general practitioner,” a family doctor with enhanced role in acute medicine, physiology, diagnostics, palliative care, research, ethics, and with added technical ability. Most importantly they are the team leaders and orchestrators (and providers) of care, and their competencies must therefore include these team-management, integration-of-care skills. Competency-based training makes this possible by explicitly identifying which skills are shared in common and which are peculiar to specific disciplines. Thus, although weaning from ventilation,²⁶ instigation of renal replacement, nutritional support, prophylaxis for venous thromboembolism, and chest pain management pathways,²⁷ among others, can be nurse led and protocol driven, the intensivist provides a strategic, integrating, and continuity role as much as a technical one. Opportunities for collaboration between critical care physicians and hospitalists can also be clarified in this manner. In this model, hierarchies become flatter, practitioners become more patient focused, and the intensivist's leadership skills must include the capacity for collaborative decision making while continuing to assume final responsibility for patient care. As nonphysician roles increase and extend, it is essential that their schemes for training be coordinated and better integrated with those for physicians, ideally starting at undergraduate level.²⁸

PRACTICAL IMPLICATIONS OF COMPETENCY-BASED TRAINING

Concerns about competency-based training include the perception that competencies describe a “craftsman” rather than a “professional” and that “being a good doctor” is too complex to be defined by lists of skills or activities.²⁹⁻³¹ This may be an artificial distinction, because both may aspire to excellence through constant practice and reflection. The professional has the privilege of self-regulation based on defined standards of practice, which emphasizes the importance of revalidation and recertification. The minimum standard for revalidation should include the competencies of a specialist, plus evidence of excellence, which may include the domains of research, teaching, professional development, role modeling, and high-quality patient care

demonstrated through processes or outcomes. A minimum safe standard is where professional training starts, not where it ends.

The *duration of training* is determined by the acquisition of competencies, not by a fixed and arbitrary period in training, although training programs will of course need to continue to set a minimum time. The practical implication is that some trainees may not meet the expected targets and will require remedial training or more focused attention. The key to this is adequate supervision by “trained trainers” supported by all senior staff. Monitoring progress is essential to avoid discovering problems too late for effective remediation, such as at the end of training, or after specialist accreditation through adverse events or clinical complaints. The cost implications of having senior faculty with time to mentor, assess, and develop their trainees is considerable. In larger programs, it becomes even more important to bridge the distance between trainer and trainee, because shift working and arduous schedules disrupt opportunities for apprentice-based relationships.

Documentation is a crucial component of training because it provides the evidence on which the trainee makes the case for being accepted as competent or, indeed, excellent. Portfolios are the responsibility of the trainee but require review by the trainer designated as mentor or supervisor for that trainee. It seems likely that most training programs will move from traditional paper-based methods to e-portfolios as technology evolves. This change brings with it both advantages and disadvantages (Box 74.1). A particular advantage of Internet-based technologies is the ability to link competencies and syllabi to the rapidly expanding repository of web-based educational resources.³² They may also make it easier to deliver educational interventions in the workplace during clinical work rather than limiting provision of education to office hours.³³

Maintenance of competence has become an increasingly regulated activity for specialists, incorporating the distinct but related processes of accredited continuing medical education (CME) or continuing professional development (CPD), appraisal, revalidation, and recertification or maintenance of certification. Standards for recertification vary widely.³⁴ Several countries now have mandated processes, including Australia, New Zealand, Canada, the United States, and from 2013 the United Kingdom. Maintenance of certification in the United States is based on demonstrating competence in six domains,³⁵ and in the United Kingdom in four domains.³⁶ The process for revalidation for intensive care specialists in the United Kingdom has recently been defined.³⁷

Access to educational materials is another important consideration. Service pressures and budgetary constraints mean that education will need to be delivered locally, supplemented by distance-learning programs combined with self-assessment. To work well, education needs to be integrated with the clinical and training environment, be available in a timely manner, and be placed in context—for example, during a ward round or immediately after seeing a patient with a particular condition. Computers and clinical decision support systems can provide this, but careful collaborative development by information technology experts, clinicians, and educators is required. Linking educational resources to competencies is a necessary step in building and

Box 74.1 E-Portfolios: Analysis of Utility

Strengths

- Facilitates remote communication between trainee and trainer
- Integrates with whole career: life long learning and revalidation
- Easy to update
- Secure central database
- Links to Internet, e-resources
- Portable: smartphone/phone/laptop
- Facilitates audit, monitoring, identifying gaps in knowledge

Weaknesses

- Data security
- Loss of passwords/access/firewalls
- Overemphasis on detail and “box ticking”
- Electronic communication not as good as face to face
- Expensive technical support and maintenance

Opportunities

- International integration
- Facilitates pedagogic research
- Update reminders/diary
- Link to educational resources
- Documentation of course attendance and skills acquisition

Threats

- Data loss, confidentiality
- Cheating
- Internet access speeds diminished with large volume of users

maintaining competency-based systems of training. It is now more common for trainees to look to smartphone applications to access knowledge and procedural guidance than traditional texts. This is both a useful and problematic innovation. The Internet allows both peer-reviewed and entirely unedited repositories of knowledge to be created, many of which are excellent, some less so.

ASSESSMENT

Workplace-based assessment of competence (Box 74.2)³⁸⁻⁴⁶ is not generally problematic for the majority of trainees, but the potential complexity of assessment becomes apparent when there is a trainee in difficulty or when an adverse assessment results in litigation or revelations of serial malpractice later in life. Why was the problem not detected earlier? Whose responsibility is it to undertake assessment? How should it be performed? How often should assessments be made? How reliable and repeatable are the methods used, and how does one deal with disagreement between different trainers?

For any program of training, a system of evaluation must exist to test the validity of the teaching method, the content,

Box 74.2 Workplace-Based Assessment Methods

Direct Observation

- Direct observation of skills (e.g., DOPS, OSATS)^{50,51}
Direct observation of a physician performing diagnostic and interventional procedures during normal (“routine”) clinical practice—used to assess the doctor-patient interaction and the process as a whole, not just the procedure itself
- Clinical evaluation exercise (CEX)^{52,53}
A “snapshot” observation of a normal (i.e., routine) clinical encounter
- Audiovisual records
Assessment of real-time video-recorded consultations using a structured rating scale
- Multisource feedback (MSF)⁴⁹
Patients’ or colleagues’ views of the physician’s professional attitudes and behavior in day-to-day practice are collected on a structured rating form; completed forms are returned to a central point and summarized. Feedback is then provided during a meeting between the doctor and the reviewer. MSF also is termed 360-degree assessment, peer assessment, or team assessment of behavior

Case Reviews and Analysis

- Case-based discussion or chart-stimulated recall
Use of an actual written record to focus structured discussion about a case
- Structured case histories
A written report summarizing a case that has been encountered and, with reference to the relevant literature, reflecting on the management of that case

DOPS, directly observed procedural skills; OSATS, objective structured assessment of technical skills.

Superscript numbers refer to specific references provided online for this chapter.

and its application. If the curriculum is to have an assessment component, it too requires regular evaluation to ensure that it remains valid, that is, repeatable and consistent between observers. The ultimate test is whether the curriculum and method of testing lead to improvements in health care. Miller’s hierarchy of learning⁴⁷ suggests that whereas undergraduate training is more focused on the acquisition of knowledge, postgraduate training places increasing importance on performance, and assessment strategies must therefore focus at the “action” level or on “what one does.” Assessments need to take into account the trainees’ abilities and previous experience, the complexity of the tasks that they perform, and the context. In a variation of the Miller pyramid, the route to becoming a true specialist might be a training ladder, with step 1 (the novice) representing the acquisition of knowledge; step 2 (the trainee) the period of training, which will vary in duration and intensity, depending on needs; step 3 (the competent new specialist) indicating independence; and step 4 (the expert) with experience and further training beyond basic competencies. The steps are not truly rigid because in reality, skills and knowledge are learned together and

experiences and practice occur at all stages in training. This schema is equally applicable to all disciplines.

Definitions of competencies serve to guide the assessment process. Descriptions of what physicians should be able to do create a benchmark against which judgments can be made of clinical performance (“does,” rather than “can do”). A range of methods and tools may be used to assess training, but assessment of physicians’ performance at work is still in its infancy.⁴⁸ Assessment must go beyond technical skills to include aspects of professionalism, attitudes, and behavior: communication skills, familiarity with current knowledge, shared decision making, respect for autonomy, and compassion. Techniques for the assessment of holistic professionalism include “360-degree assessment,” also called multisource feedback.^{49,50} This technique involves actively seeking the opinion of others on the team, both one’s peers and junior colleagues and, where appropriate, patients and relatives, about one’s performance.

During training these assessments should be formative—that is, they should contribute to learning and not be a final pass/fail judgment. This traditional “apprentice-master” model requires frequent observation during routine clinical work by an experienced trainer and works well for the majority of trainees. However, the model may need to be supplemented by formal methods involving more objective assessment of performance. The assessments should be documented in the trainee’s portfolio and combined with annual appraisal. A more novel technique is based on video recording of team behaviors during ward rounds.⁵¹

Institutions need to allow protected time for trainers to be trained in formal assessment techniques and time to carry them out within employment contracts. It is important that all members of the team contribute to teaching and to training assessments; it cannot be the sole responsibility of one individual.

DELIVERING TRAINING AND ASSESSMENT IN THE WORKPLACE: ROLE OF SIMULATION

Simulators in health care are not a new concept. The Romans had birthing phantoms made from various leathers and bone to teach midwifery. Indeed early vivisectionists would have claimed operations on animals improved performance of the surgeon when dealing with patients. Simulated clinical environments and patient or equipment simulators have long seemed a highly effective solution to the problems of providing effective individual and team training. Modern medical simulators come in various guises, from simple anatomic models, to part task trainers, to complex virtual reality systems (Table 74.1). However, the most important part of a simulator is not the technology, but the faculty who write the scenario and, more importantly, debrief the students after simulation. Simulated cases lend themselves well to acute care settings. Here, a number of discrete interventions carried out on a single “patient” by various members of the team can be evaluated, subsequently can be viewed in private or during group discussion, and can be of assistance in understanding team working. Rare critical events associated with high rates of mortality or morbidity will not be encountered with

Table 74.1 Categories of Simulators Used in Medicine

Simulator Type	Description	Example	Uses	Relative Cost
Diagrams and static models	Basic anatomic representations	Circulatory system	Largely illustrative	Low
Part task trainers	Anatomically correct models that have simple moving parts demonstrating one or more processes	Airway manikin with inflatable bladders representing lungs	Clinical skills and procedural training to look at individual tasks	Low
Computer simulation software	Computer- or web-based programs that can recreate physiologic processes and the responses to interventions	ACLS Sim*	Rehearsal of treatment algorithms and practice in applying knowledge	Low
Complex task trainers	Anatomically correct models with a number of elements that can be manipulated and respond to manipulation to produce physiologically credible effects	Resusci-Annie† ALS training manikins with inflatable lungs, rhythm generators for electrocardiographic analysis	More complex scenario-based training when multiple interventions are required	Medium
Intermediate-fidelity manikins	Anatomically correct human manikins that demonstrate automated and instructor-driven responses to a range of interventions	Instructor-driven manikins: Laerdal Sim Man‡	Complex multiuser scenario-based training and assessment	Medium to high
High-fidelity manikins	Anatomically correct human manikins equipped with response algorithms that can mimic the physiologic responses of numerous patient types to a range of interventions and environmental changes	Instructor- and algorithm-driven manikins: Meti-Human Patient Simulator (Meti-HPS)§	Complex multiuser scenario-based training and assessment	High
Virtual (VR) reality trainers	Simple VR trainers are available that largely resemble complex task trainers Experimental systems will ultimately be able to recreate any clinical situation in any environment.	Training and assessing complex tasks Full-blown recreations of events True telemedicine		Very high

sufficient frequency in normal clinical practice for all clinicians to gain proficiency in their avoidance and management, but they can easily be incorporated in simulations. This ability to re create complex and infrequent but highly significant clinical scenarios improves the consistency and repeatability of assessment.

Critical incident training has been carried out in industry for many years, most notably in aviation. High-fidelity aircraft simulators have been in routine use by flight and cabin crews for many years. Human patient simulators (HPS) offer physiologically accurate responses, haptic feedback, integration with patient records, and high-quality closed

capture video recording. Such intermediate and high-fidelity manikins are freely and widely available. However, there remains little standardization in the way they are used for training or assessment. Also, the considerable setup fees are dwarfed by the faculty costs in using these systems to their best. Often, then, items bought with the best intention are not used as part of any integrated training scheme and exist as novelty.

A number of studies have demonstrated that knowledge acquisition is faster when using simulations to support traditional learning methods. This context-specific learning also allows better retention of knowledge but only up to a

point. Skills acquisition is also faster if first taught on simulators, but those taught on more conventional lines soon catch up, and after a period of similar clinical practice, differences in performance are negligible.

Areas in which simulators are frequently used are the advanced life support courses, the Fundamentals of Critical Care Support course developed by the Society of Critical Care Medicine (SCCM),⁵² and the European Society of Intensive Care Medicine's PACT (Patient-centered Acute Care Training) program.⁵³

The pressures to deliver service rather than training, the reduction in trainees' working hours, and the need for quality assurance in training have led to more effective teaching methods and credible assessment tools. Simulation assessment is efficient, repeatable, and reliable; and the scenarios can be well integrated with the clinical environment to allow short and focused training opportunities linked to debriefing.

SUMMARY

Critical care medicine provides important training opportunities for all clinicians and is an ideal environment in which to gain proficiency in technical skills, team working, ethics, and professionalism. Training in ICM should start at the undergraduate level to maximize these opportunities. A universal set of core competencies can be expanded according to local requirements and be used to foster shared team-based skills in acute care across different disciplines. Health care systems need to invest in education in the workplace, with access to information integrated with clinical work, support for trainers, and the development of workplace-based methods for assessment. Portfolios should become reflective life long learning documents for specialists, as much as for trainees. Pedagogic research is needed to evaluate education programs as quality improvement implementation devices for translating research knowledge into better patient care.

KEY POINTS

- Critical care training is heterogeneous in access, process, and certification.
- There appears to be growing consensus on the core knowledge and skills needed to practice intensive care.
- Internationally recognized competency-based training should ensure a minimum knowledge and skill base for specialists and allow meaningful comparisons.
- Continuous workplace assessments and appraisals will be needed for revalidation.

KEY POINTS (Continued)

- Service delivery pressures will require greater use of specialist nonphysician grades to operate within protocol-driven frameworks. Competency-based training will allow integration of their training with that of physicians.
- Simulators and simulated environments will increasingly be used for team training and to adequately prepare staff to deal with uncommon situations.
- The reduced length of training will lead to better trained but less experienced individuals entering the specialist workforce. This emphasizes the need for continuing medical education integrated with clinical practice and formal "protected" training sessions conducted by experienced clinical educators.
- There are significant resource implications associated with life long training and assessment schemes with mutual recognition across international borders.

Diagnosis and Management of Liver Failure in the Adult

Nick Murphy

CHAPTER OUTLINE

DECOMPENSATION OF CHRONIC LIVER DISEASE

Precipitating Factors of Acute on Chronic Liver Failure

Supportive Management in Critical Care

ACUTE (FULMINANT) LIVER FAILURE

Etiology

Clinical Course

Management

Artificial Liver Support

Liver Transplantation

Liver failure is most often encountered as result of decompensation of chronic liver disease but can also occur de novo in patients with previously normal livers. These patients are often described as having fulminant or acute liver failure depending on the definition used.

Liver failure is characterized by a constellation of physical signs and symptoms including jaundice, coagulopathy, and encephalopathy. Not all of these need be present for a diagnosis to be made, but as the syndrome progresses they are usually present to varying degrees. Liver failure progresses to multiple organ failure and ultimately death in a large proportion of patients, and supportive care plus removal of the primary cause is the mainstay of treatment. In a small group liver transplantation may be indicated. Liver support systems are being actively investigated and may, in the future, have the ability to bridge a patient to recovery or transplantation.

DECOMPENSATION OF CHRONIC LIVER DISEASE

“Decompensation” in cirrhosis of the liver is a term used to describe the onset of visible signs of portal hypertension such as the development of ascites and variceal bleeding. These signs and symptoms can also be described as “symptomatic” cirrhosis, with the onset of liver failure in symptomatic cirrhosis described as “decompensation.” One often leads to the other, but for the purposes of this chapter decompensation will refer to the onset of liver failure.

The pathologic basis of acute decompensation in chronic liver disease or acute on chronic liver failure (AoCLF) is incompletely understood but is thought to be precipitated by systemic inflammation, and if looked for hard enough, some signs or symptoms of infection will be seen in most patients.^{1,2} Patients with well-compensated cirrhosis often decompensate following a defined event. The precipitants can be split into two types: (1) those due to direct liver insult, such as ischemia, a toxic insult such as alcohol, or a superimposed viral infection and (2) those in which the liver is affected as a bystander in a systemic inflammatory process, such as following an episode of sepsis or a gastrointestinal bleed. This can be contrasted to the progressive liver failure of end-stage cirrhosis. Both present with similar clinical pictures but in AoCLF there remains the possibility of improvement and reversibility, and if these patients do recover they end up back on the previous mortality trajectory.^{1,2}

Differentiating between the two is difficult but the presence of a precipitating factor and history can be useful. In patients with end-stage liver cirrhosis there is often a history of gradual deterioration in biochemical parameters, clinical status, and other organ function whereas in AoCLF there is often an acute deterioration. Organ support in the former setting is of dubious utility as it is almost always futile (Fig. 75.1).

One group has proposed a working definition for AoCLF as “acute deterioration in liver function over a period of 2-4 weeks, usually associated with a precipitating event, leading to severe deterioration in clinical status, with jaundice and hepatic encephalopathy and or hepatorenal syndrome (HRS), with a high SOFA/APACHE II score.”¹

Figure 75.1 Graphs A and B represent the trajectory of liver function in cirrhosis. B is indicative of a patient with progressive end-stage disease. A has a more shallow trajectory until there is a precipitating event, at which time either graphs C or D can be followed. C recovers with intervention back to the previous trajectory, but D does not.

AoCLF often occurs with multiple organ dysfunction. This may be because of the underlying precipitating event such as pneumonia or bacterial peritonitis or as a result of the severe deterioration in liver function. Often it is difficult to distinguish which came first. Renal failure is the most common organ failure associated with AoCLF and it is the severity of organ dysfunction that dictates the outcome.³

PRECIPITATING FACTORS OF ACUTE ON CHRONIC LIVER FAILURE

ALCOHOLIC HEPATITIS

Alcoholic hepatitis is a common manifestation of alcohol abuse. Between 20% and 30% of heavy drinkers will present with it at some time. The clinical picture is variable from a relatively mild syndrome associated with loss of appetite, nausea, and vomiting with right upper quadrant pain to severe life-threatening liver decompensation, but the most obvious sign is the sudden onset of jaundice, and this can be the first indication of liver disease in a heavy drinker. Overall, following first presentation, 35% to 50% of patients will die within the first month of diagnosis.⁴ It usually presents following a bout of heavy drinking and often occurs on a background of cirrhosis. Patients frequently deteriorate after stopping alcohol. This may be due to the immunosuppressive effects of alcohol. In patients without cirrhosis abstinence and nutritional support can lead to a marked improvement in liver function over time.

Features suggestive of malnutrition such as muscle wasting and vitamin deficiency are seen commonly. In severe decompensation other intercurrent illnesses such as pneumonia or urinary tract infection or a gastrointestinal bleed are often present. Systemic inflammation may be the precipitant of decompensation in these patients.⁵

PORTAL HYPERTENSIVE BLEEDING

Portal hypertension is a significant complication of chronic liver disease leading to the formation of portosystemic

collateral vessels. Of these vessels, the most significant clinically are those that occur in the wall of the stomach and esophagus. In patients with portal hypertension as a result of cirrhosis the development of gastrointestinal varices occurs in approximately 60% at the time of diagnosis.¹¹ The incidence of the first acute bleed in an unselected patient is relatively low at about 5% per year but it can be catastrophic when it occurs.¹² The mortality rate associated with the event has fallen over the past 20 years from approximately 30% to 50% to about 20% and control of the initial bleeding episode is achieved in about 90% of patients.¹³ Half of all fatalities occur in the first 5 days following an acute bleed and about half of them are due to uncontrolled bleeding and the rest are due to multiple organ failure. This pattern remains the same when mortality rate in the first 6 weeks following the first bleed is examined.¹³

The use of antibiotic prophylaxis has been shown to reduce the incidence of infection in this group of patients and to improve short-term mortality rate.^{20,21} It has been proposed that infection is the precipitant to an acute increase in portal pressure that may trigger bleeding.²²

BACTERIAL PERITONITIS

Patients with chronic liver disease are at increased risk of infection. The immunosuppression associated with chronic liver disease is incompletely understood but relates to a range of factors including an impaired innate and adaptive immune response.^{23,24}

In cirrhotic patients with ascites, decompensation to liver failure is often precipitated by infection. Bacterial peritonitis is a common and severe complication. It can be completely asymptomatic but can present with a range of symptoms and signs including local signs of peritonitis, abdominal pain, diarrhea, and signs of systemic inflammation such as fever, rigors, raised white blood cell count, hypotension, and tachycardia.²⁵

Bacterial peritonitis is often spontaneous, without any obvious source, although it can be secondary to other intra-abdominal disease. It is generally caused by aerobic gram-negative bacteria, although gram-positive bacteria including methicillin-resistant *Staphylococcus aureus* (MRSA) should be suspected if there is treatment failure, especially if the patient has been taking prophylactic antibiotics.²⁶ In any patient with ascites and decompensation of liver disease, spontaneous bacterial peritonitis (SBP) should be suspected. Diagnosis is demonstrated by sampling of the ascitic fluid. An absolute leukocyte count in ascitic fluid of greater than 250/ μ L is diagnostic. Antibiotics should be started as soon as SBP is suspected, following blood culture and a diagnostic ascitic tap. Empiric broad-spectrum antibiotic coverage for gram-negative and MRSA organisms (depending on local prevalence) should be started until cultures are available.

Renal failure is a significant complication of SBP in patients with cirrhosis and is discussed later. The use of human albumin solution (HAS) in SBP has been shown to reduce the incidence of progression to renal failure and should be considered in this setting.²⁵

SUPPORTIVE MANAGEMENT IN CRITICAL CARE

The presentation of AoCLD will depend on the precipitating event or events but the clinical picture and pattern of

In alcoholic hepatitis liver enzymes are moderately raised with an aspartate aminotransferase (AST) rarely greater than 300 IU. The ratio of AST to alanine aminotransferase (ALT) is usually raised to greater than 2.⁶ A high white blood cell count and bilirubin are also typical. The liver is usually enlarged and fatty on ultrasound. Portal hypertension often complicates the clinical picture, presenting as worsening of ascites. Assessment of filling pressures can be difficult if ascites is tense. Further hemodynamic monitoring is recommended if there is any doubt regarding filling status or if cardiac output is thought to be compromised.

Strictly speaking, liver biopsy is required to make the diagnosis of alcoholic hepatitis and is often performed to assess the extent of fibrosis, although it is not required for acute management. Demonstrated under light microscopy, the Mallory's hyaline and a neutrophil infiltration (the amount of which is a marker of severity and prognosis), necrosis of hepatocytes, collagen deposition, and fatty change establish the diagnosis.

The prognosis of patients with alcoholic hepatitis depends on the severity of the disease. Risk stratification is important, both in defining the indications for the use of specific pharmacologic agents aimed at the interruption of progression and in clinical research. Serum markers and liver histologic findings provide the best means for risk stratification, the presence of cirrhosis being a poor marker.⁷ In many cases,

however, biopsy is precluded because of the risks of bleeding. Serum bilirubin, coagulation parameters, and creatinine have been shown to predict outcome and have been combined into several scoring systems; the discriminative function (DF); Child, Turcotte, Pugh (CTP); the Mayo end-stage liver disease (MELD) score; and the Glasgow Alcoholic Hepatitis (GAH) score have been used to evaluate outcome. Of these, the MELD score appears to offer the best prediction of mortality risk because of the inclusion of renal function (creatinine) as well as liver function; renal deterioration in this setting has a particularly poor prognosis.⁸ Standard critical care prognostic scores have also been used to assess the prognosis of patients with decompensated chronic liver disease of any cause. The sequential organ failure (SOFA) score has been shown to provide useful prognostic information.^{1,9}

In early disease, abstinence and good nutrition, including supplementation with B vitamins, is the mainstay of management. In severe disease, progression to hepatic encephalopathy and organ failure can be rapid. In addition to general supportive care, specific therapies have been used in an attempt to halt and reverse the hepatic inflammation and prevent the fall into multiple organ failure and ultimately death. Of these, and pentoxifylline have been the most extensively studied.¹⁰

Control of bleeding episodes is via direct endoscopic therapy, usually in the form of band ligation in the case of esophageal varices.¹⁴ Terlipressin, a synthetic analog of vasopressin, can be used as an adjunct to band ligation. Terlipressin induces splanchnic vasoconstriction and reduces portal pressure and has been shown to reduce mortality rate.¹⁵ There is some evidence that somatostatin may reduce the amount of blood transfused but the evidence is weak.¹⁶ Uncontrolled bleeding due to either failed endoscopic or pharmacologic therapy or when resources do not allow immediate endoscopic therapy may be managed with balloon tamponade of the stomach or esophageal varices. Primary control of esophageal varices is usually successful but balloons should not be inflated for more than 12 hours because of the risks of mucosal necrosis. Care should be exercised when inserting and inflating a Sengstaken-Blakemore or Minnesota tube because perforation of the esophagus is usually fatal in this setting. Following control with the insertion of a balloon tamponade device, further endoscopic therapy, surgical shunting, or transjugular intrahepatic portosystemic stent shunts (TIPS) may be attempted. Of the shunt procedures used TIPS is the most commonly attempted, where technical skills are available. The procedure involves decompressing the portal circulation into the hepatic vein via a stent inserted percutaneously through the liver via the internal jugular vein. The procedure is a very successful salvage therapy for controlling bleeding but can induce certain complications, including (a) volume overload as a result of portal shunting into the right atrium, which can induce heart failure; (b) bypassing the portal circulation resulting in ischemic liver injury and, rarely, liver failure; and (c) worsening of encephalopathy grade (the

most common complication) resulting in failure to wake from the procedure, the need for extended ventilation, and the risk of hospital-acquired infection. There have not yet been any controlled trials of TIPS as salvage therapy in this setting and it is unclear what role TIPS has in the management of acute bleeding varices as it may just result in prolongation of the dying process. Despite better prevention of rebleeding when compared to endoscopic therapy in patients with bleeding varices, a mortality benefit cannot be shown with TIPS.¹⁷ Recently, Garcia-Pagan and colleagues have shown that TIPS, not done as salvage therapy, but used as a primary form of therapy once the initial bleed has been controlled, results in a dramatic reduction in rebleeding rates and mortality rates.¹⁸ This study has huge resource implications and needs to be repeated.

Coagulation abnormalities are commonly present in patients with acutely bleeding varices, and abnormalities in clotting factors have been shown to be independent prognostic factors in patients with esophageal varices. Attempts to treat coagulation abnormalities with clotting components should be undertaken during an acute bleed to include fresh frozen plasma (FFP) and platelets targeted to correct abnormal partial thromboplastin time (PTT) and platelet count. Activated factor VII has also been investigated in this setting. The authors showed that in patients with worse cirrhosis, as defined by Child-Pugh grades B and C, recombinant activated factor VII (rFVIIa) increased the chances of controlling the bleeding, although a more recent study by the same group shows no difference between groups.¹⁹

Bleeding from varices is associated with infection. Between 35% and 60% of cirrhotic patients with bleeding varices have documented infection over the following 2 weeks.²⁰

organ failure will on the whole look very similar. Hyperbilirubinemia and the resulting jaundice are almost universal, as are other biochemical manifestations of poor liver function. Plasma protein production is deranged, leading to a prolongation of prothrombin time and hypoalbuminemia. Thrombocytopenia due to hypersplenism and sepsis is also characteristic. The effects on the coagulation system are complex, however, as there is a concurrent reduction in the production of endogenous anticoagulant proteins in the liver resulting in a relative rebalancing. Infection leads to consumption of factors and platelets and so the use of thromboelastography is recommended in bleeding patients. Lower levels of factors can result in difficulties maintaining coagulation during times of stress, particularly during infections, and evidence of a heparin-like effect has been shown.²⁷ It is also interesting to note that the incidence of thromboembolism is not lower in patients with cirrhosis even in the setting of a prolonged international normalization ratio (INR), suggesting that standard measures of coagulation are unreliable.²⁸

The pattern of circulatory changes associated with cirrhosis is distinctive. Hypotension and an increase in cardiac output are typical, resulting in a hyperdynamic circulation. Peripheral vasodilatation, however, is not distributed evenly and occurs mainly in the splanchnic circulation as a result of sinusoidal portal hypertension. Splanchnic vasodilatation results in effective arterial underfilling with the resulting activation of compensatory mechanisms.²⁹ During decompensation circulatory changes become more pronounced with an increase in portal pressure; systemic vasodilatation worsens and blood pressure drops further and becomes less responsive to vasopressor support. Recent work shows that cardiac output may fall in those who develop hepatorenal failure, as do cardiac filling pressures and pulmonary artery pressure. These changes point toward some form of cardiac depressant factor associated with decompensation.²⁹ There is a reduction in intrarenal blood flow, due to the activation of compensatory mechanisms designed to maintain arterial volume, such as the renin-angiotensin system and sympathetic nervous system. This results in a further reduction in glomerular filtration rate (GFR) and urine output. Cardiac function may be further compromised by liver failure-associated cardiomyopathy, which is manifested by a low or normal cardiac output in the setting of reduced afterload.³⁰ There may also be a relative hypovolemia in the setting of a normal or raised central venous pressure because of raised intra-abdominal pressure due to ascites. Echocardiography is very helpful in the delineation of any cardiac dysfunction and can help assess pulmonary artery pressure to assess if the patient has portopulmonary hypertension.³¹ A pulmonary artery (PA) catheter should be used if there is any doubt.

Acute kidney injury (AKI) is the most common form of organ dysfunction seen in patients with AoCLF and has significant attributable mortality risk.³² There are four main causes: those associated with bacterial infection are the most common, followed by hypovolemia and parenchymal disease, with hepatorenal failure the least common.³ However, hepatorenal failure has a particularly poor outcome. The diagnosis of AKI in the setting of liver disease is problematic, as conventional measures of renal function are less indicative of renal function.

Hepatorenal syndrome is a severe and progressive reduction in renal function in patients with severe liver disease and presents in two clinical patterns, type 1 and type 2. Hepatorenal syndrome represents the renovascular response to the profound circulatory changes associated with cirrhosis. Type 2 HRS is characterized by a less severe and more gradual reduction in renal function associated with diuretic-resistant ascites and hyponatremia. It is usually seen in association with end-stage cirrhosis. Type 1 HRS is characterized by the rapid decline in renal function defined as a 100% increase in serum creatinine to a level greater than 221 mmol/L or a 50% reduction in 24-hour creatinine clearance to a level less than 20 mL/minute in less than 2 weeks.³³ Initially HRS is potentially reversible as the kidneys are functionally normal; however, the longer the circulatory changes last without reestablishing the GFR, the less likely are the kidneys to recover, and the distinction between HRS and acute tubular necrosis becomes less clear. In most patients there is a precipitating event, while in others it occurs in close proximity to an event such as the resolution of SBP. The diagnosis is made by the exclusion of other causes and is based on criteria developed by the International Ascites Club.³³

AKI in the setting of AoCLF is managed along conventional lines. Hypovolemia is corrected and diuretics are stopped. Potentially nephrotoxic drugs are stopped, and the underlying precipitating event is managed.

Until recently there was no effective treatment for patients with HRS other than liver transplantation, but over the past 15 years observational and interventional studies have shown that countering the compensatory circulatory changes that promote intrarenal vasoconstriction with use of systemic and selective vasoconstrictors plus plasma volume expansion with albumin can lead to significant improvement in renal function.³⁴ The aim of therapy is to focus vasoconstriction on the dilated splanchnic vessels, resulting in a redistribution of the blood volume back into the systemic arterial circulation. Over time this results in suppression of the compensatory mechanisms; a reduction in plasma renin activity, sympathetic activity, and circulating catecholamines; and an associated increase in GFR, sodium excretion, and urine output.³⁵ Many different vasoconstrictors have been tried in this setting. The drug most commonly studied is terlipressin and it is often given with 20% human albumin solution (HAS). This approach has been subjected to a randomized controlled clinical trial in which the addition of albumin was associated with an improvement in outcome.³⁶ Evidence suggests that vasoconstrictor therapy, with or without plasma volume expansion, results in an improvement in renal function in about a third of patients with type I HRS. The best predictors of response to therapy is the baseline serum creatinine, and those who do respond have a significant rise in their arterial pressure.^{34,37}

Hepatic encephalopathy (HE) is almost universal during decompensation of chronic liver disease and is characterized by loss of normal day/night differentiation, confusion, somnolence, asterixis, hyperreflexia, and progression to coma. It is reversible in the event of recovery of liver function or removal of the precipitating event. The etiology of hepatic encephalopathy is incompletely understood but relates to the inability of the failing liver to clear circulating toxins, most notably ammonia. There are other important

factors including minor degrees of cerebral edema and systemic inflammation. Interaction of these components leads to the profound levels of encephalopathy seen in AoCLF.

Ammonia production in the gut is important in the pathogenesis. Ammonia is usually cleared from the portal circulation in the liver. The mainstays of treatment are colonic cleansing with enemas and enteral disaccharides such as lactulose. Both of these procedures have been shown to improve encephalopathy grades. The restriction of protein, once fashionable in patients with liver disease, is contraindicated. The majority of these patients are malnourished and adequate enteral nutrition is essential.³⁸

Patients with AoCLD and high grades of HE will require intubation and ventilation, if not because of hypoxia, then to allow airway protection. Airway protection is most frequently needed in patients with bleeding esophageal or gastric varices requiring endoscopic therapy for large volume hematemesis in the presence of HE and a difficult or prolonged endoscopic procedure. Patients with AoCLD are usually exquisitely sensitive to sedative and anesthetic agents. Even small doses of benzodiazepines can cause prolonged coma. Care should be exercised in their use and shorter-acting agents such as propofol are preferred.

Large volume paracentesis should be considered in any patient with tense ascites. There is evidence that large volume paracentesis improves lung mechanics and oxygenation in nonventilated patients but data in ventilated patients are lacking.³⁹⁻⁴¹ Hepatic hydrothorax is a persistent pleural effusion, almost always associated with ascites, usually on the right side of the chest. It can be massive in size, containing many liters of fluid, and is thought to be due to communication from the peritoneum. Management can be difficult. Direct drainage with thoracentesis is usually inadvisable as the fluid accumulation is persistent, leading to continued need for chest tube placement, which carries the risk of infection. Management should be directed at the ascites and includes diuretics, salt restriction, and paracentesis. TIPS can be used to control both ascites and hydrothorax but is associated with worsening encephalopathy grade in some patients.⁴²

Adrenal dysfunction in patients with critical illness has been documented extensively, particularly in patients with septic shock.⁴³ Studies have suggested an improvement in outcome with steroid use but subsequent investigations have been less clear. Currently recommendations suggest steroid treatment should not be based on adrenal stimulation and should be reserved for those with vasopressor-resistant septic shock or early acute respiratory distress syndrome (ARDS) within 14 days of onset.⁴³ Patients with liver failure have been shown to have a high incidence of adrenal suppression as well, although it is not clear if this has a different etiology to other critically ill patients. Patients with adrenal suppression have worse hepatic and renal function, more organ failure, and a higher intensive care unit (ICU) and hospital mortality rate.⁴⁴ There remains, however, a lack of consensus regarding definitions of adrenal dysfunction and appropriate testing in patients with liver disease and in which patients require treatment.⁴⁵ However, in patients with cirrhosis and septic shock admitted to the ICU with adrenal insufficiency as defined by a suboptimal response to ACTH stimulation, replacement of hydrocortisone (50 mg every 6 hours) results in a higher incidence of shock resolution and

Figure 75.2 This graph shows the relative mortality rates associated with the number of failing organs as defined by a SOFA (sequential organ failure) score of greater than 3. In patients with cirrhosis (yellow bars) there is an excess mortality rate at each position. Blue bars, unselected group.

hospital survival when compared to historical control subjects.⁴⁶

OUTCOME AND DATA ON ICU USE IN DECOMPENSATED CIRRHOSIS

Despite ICU care, the outcome in patients with decompensated cirrhosis is poor. In one study overall cumulative mortality rates were 36% in the critical care unit, 46% in the hospital, and 56% at 6-month follow-up.⁴⁷

In patients who require organ support within the critical care environment a number of observations can be made. Derangement of acute physiology at admission is a predictor of outcome, as it is for unselected patients admitted to the ICU.⁴⁸ In addition, the number of organs requiring support also is predictive of outcome, as it is in unselected patients.^{47,49} If you compare the number of organs failing (defined as an organ-specific SOFA score greater than 3) there is an excess mortality rate associated with cirrhosis when compared to an unselected group (Fig. 75.2).⁵⁰ Patients with cirrhosis and three organ systems requiring support have a mortality rate in excess of 90% in some studies.⁴⁹ Severity of liver disease at admission has a significant bearing on outcome irrespective of indication for admission to the ICU.^{49,51}

ACUTE (FULMINANT) LIVER FAILURE

Acute liver failure (ALF) is a syndrome manifested by the rapid cessation of normal function in individuals with previously normal livers. The rate of decline in function dictates the manner in which the syndrome manifests and influences the outcome. The cause is the main influence on the rate of progression and the likelihood of spontaneous recovery.⁵²

The pathologic basis of the massive hepatic necrosis was described in detail by Lucké and Mallory following the Second World War in 1946.⁵³ The presence of the American

army in East Asia and Africa resulted in exposure to both epidemic and serum hepatitis, and data regarding the clinical course of the syndrome and its pathologic features were collated via the army medical services.

In 1970 Trey and Davidson introduced the term *fulminant hepatic failure* (FHF) to encompass the current clinicopathologic understanding of the syndrome.⁵⁴ This definition was an attempt to encapsulate the clinical course and to differentiate it from decompensation of chronic liver disease. They described a syndrome of rapidly progressing liver failure (within 8 weeks) in which the defining point was the onset of hepatic encephalopathy following the onset of symptoms in someone without previous liver disease. They make the point that the syndrome is potentially reversible in some patients. This definition is still used today; however, it has become clear that this definition is too narrow and that subgroups exist. This point is important as these subgroups predict the likely prognosis and potential for survival without a liver transplant.⁵²

The rate of progression from the onset of jaundice or other initial symptoms (such as fatigue or acute viral illness) to development of encephalopathy is used to define subgroups. This in part relates to the cause of liver failure and to the way the pathologic expression of the pattern of organ failure presents. For example, patients with significant acetaminophen-induced hepatotoxicity will generally present with liver failure within 7 days of ingestion, unless ingestion was staggered over a period of time when the timing of liver insult is difficult to define. Patients often present with cardiovascular collapse and renal failure before they become encephalopathic. In contrast, patients presenting with seronegative hepatitis (unknown cause) can have a very variable presentation, some with a prolonged illness over a period of months, resulting in a patient who is deeply jaundiced with evidence of portal hypertension, such as ascites, at the onset of encephalopathy, and others with a relatively short presentation period. These two extreme ends of the syndrome split the group into hyperacute and subacute, with ALF in the middle. Interestingly, it is the hyperacute group that has the best chance for spontaneous recovery, although this group has the highest risk of cerebral edema. The subacute group has the worse prognosis with medical management alone.⁵²

ALF is rare, with about 1 to 6 cases per 1 million of the population in the developed world.⁵⁵ The incidence in the rest of the world is less clear because of the paucity of data (Box 75.1).

Box 75.1 Hyperacute, Acute, and Subacute Liver Failure

Hyperacute liver failure

- Jaundice to encephalopathy within 7 days—usually secondary to paracetamol hepatotoxicity

Acute liver failure

- Jaundice to encephalopathy in 8 to 28 days

Subacute liver failure

- Jaundice to encephalopathy in 29 days to 6 months

ETIOLOGY

Worldwide, and in the developing world in particular, approximately 95% to 100% of patients presenting with ALF will have viral hepatitis.⁵⁶ Within the United Kingdom and as recently reported in the United States, paracetamol (acetaminophen) hepatotoxicity is the leading cause of ALF. This is followed by liver failure of unknown cause or seronegative hepatitis.^{57,58}

The pattern of ALF within the United Kingdom and United States has been changing over the past 30 years.^{57,58} Up until the late 1990s, the rate of hospital admission due to paracetamol ingestion had risen year by year. In the United Kingdom paracetamol overdose (POD) is usually due to deliberate self-harm. In contrast, the U.S. data suggest that over half of all patients with ALF due to POD were due to therapeutic misadventure. Some doubts have been expressed regarding this interpretation as misadventure in some cases that appear to be occult suicide attempts.^{58,59}

In 1998 legislation was introduced in the United Kingdom to restrict the over-the-counter sale of paracetamol to 16 tablets from most retail outlets and 32 from pharmacies in the form of blister packs. Interpretation of the effects of the legislation have proved to be complex, in a large part because there were no prospective audits initiated at the time to study it. Early interpretation suggested that admissions to hospital, severe liver toxicity, and transplantation for POD fell.⁶⁰ The picture is more complex, though. Death rates have fallen; however, much of this reduction can be related to the withdrawal of co-proxamol during the mid-2000s. Co-proxamol, a combination of paracetamol and dextropropoxyphene (a mild opioid), was a prescription-only medication associated with a high degree of fatality if taken in overdose, most of this out of hospital and attributed to the effects of dextropropoxyphene on respiratory depression.⁶¹ Admission to hospital because of POD has continued to rise year by year but the number of pills taken on average has fallen and so the case fatality rate is lower. The numbers of patients being referred to transplant centers is also lower than before the legislation, but the number of patients transplanted has remained about the same, indicating the small number of determined overdoses and misadventure cases has remained relatively stable.

In the United Kingdom and the United States, the incidence of acute hepatitis A virus (HAV) and hepatitis B virus (HBV) infection has fallen dramatically since the 1980s^{57,58} (Figs. 75.3 and 75.4).

Less than 1% of acute hepatitis A or B progress to ALF. In the United States and United Kingdom, as a proportion of the total, the number of admissions with ALF due to viral hepatitis has fallen steadily and is currently responsible for less than 5% of all admissions in the United Kingdom and 11% in the United States.^{57,58}

Indeterminate hepatitis (non-A to E hepatitis, seronegative ALF, non-A/non-B hepatitis) is often presumed to be viral in origin and is the most common presentation excluding POD in the United Kingdom and United States along with viral hepatitis in the developing world. It is a diagnosis of exclusion and, as diagnostic capabilities improve, is falling in incidence in some centers.⁵⁷

ACETAMINOPHEN (PARACETAMOL)

Acetaminophen-induced liver failure is the cause of the vast majority of hyperacute liver failure. Acetaminophen poisoning is a common cause of presentation to acute and emergency departments in the United Kingdom and United States; however, the case progression to ALF following paracetamol ingestion is rare at just 0.6% of all presentations in the United Kingdom.⁶²

It was in the mid-1960s that the main mechanisms of paracetamol-induced liver injury were elucidated. The

scheme outline by various groups revealed the production of electrophilic quinone imine (*N*-acetyl-*p*-benzoquinone imine, NAPQI), which covalently binds to hepatic proteins, was central to the resultant centrilobular necrosis seen following poisoning. The two major pathways for metabolism are the glucuronidation and sulfation of the phenolic group, with the metabolites produced excreted in the urine. In therapeutic doses approximately 80% of the drug is metabolized via these two pathways and 5% to 10% is excreted unchanged in the urine. The remainder is

metabolized via the hepatic mixed function oxidase, cytochrome P-450, to produce NAPQI.

Following poisoning the half-life of acetaminophen is greatly prolonged because of the saturation of glucuronidation and sulfate conjugation. As a result, there is an increase in the quantity of NAPQI produced. NAPQI is extremely reactive in biologic systems and has a short half-life. Following poisoning, reaction of NAPQI occurs within the centrilobular portions of the liver and leads to necrosis in experimental models. It reacts with cellular constituents in a covalent and noncovalent manner. The exact mechanisms by which NAPQI induces cell death are incompletely understood but include the deactivation of critical cellular proteins, the induction of reactive oxygen species, and the activation of Kupffer cells.⁶³ The loss of regulatory protein function results in abnormal calcium homeostasis and resultant energy failure within the cell and mitochondria.⁶³ Other events such as noncovalent interaction with intracellular signaling and lipid peroxidation also contribute to the toxicity of this molecule. Following this primary toxic phase there is a secondary or extrinsic phase. This extrinsic phase is equated with the recruitment of immune cells to the liver. The liver is one of the major immune organs of the body. Up to 35% of the liver is made up of nonparenchymal cells, including endothelium, Kupffer cells, and resident lymphocytes. These cells, together with macrophages within the liver, perform a major role in immune regulation and in the filtering of antigens from the gut contents via the portal circulation. They are also implicated in the pathologic processes that occur following liver insult. Massive activation of immune cells in response to the intrinsic cellular damage induces the release of cytokines and chemokines both locally and into the systemic circulation.^{64,65}

The pathophysiologic consequences of severe liver injury result from a combination of factors, including the release of cytokines and other inflammatory molecules resulting from the necrosis of hepatocytes and activation of local and systemic immune cells, and from the loss of metabolic activity related to a critical reduction in liver cell mass. The relative contribution of these factors is not completely clear but is debated and has led to attempts at therapy including temporizing hepatectomy and nonbiologic liver assist devices.

The minimum dose that can induce hepatic damage appears to be about 125 mg/kg. This represents 15500-mg tablets in a 60-kg individual, although hepatic necrosis has been recorded at much lower doses, especially if associated with hepatic enzyme induction. Doses above 250 mg/kg (30500-mg tablets in a 60-kg individual) will often produce damage, and doses in excess of 350 mg/kg invariably produce significant damage.⁶⁶

The symptoms over the first 24 hours following a significant intake of paracetamol, irrespective of amount ingested, are usually nausea and vomiting. During the following 4 to 5 days, if liver failure ensues, there is a gradual worsening of the patient's general condition. Those with significant overdose should be admitted to the hospital and monitored closely.

The antidote for acetaminophen poisoning is *N*-acetylcysteine (NAC). It provides complete protection against hepatotoxicity if given within 12 hours of nonstaggered ingestion.⁶⁷ Within 12 hours, if the time from ingestion

is known with certainty and a plasma acetaminophen level is obtained, reference can be made to the nomogram to see if the potential for hepatotoxicity is present. The nomograms are unreliable if the time from ingestion is uncertain or if there was staggered ingestion over a period of time, as often occurs with therapeutic misadventure or repeated overdose. The use of alcohol often accompanies ingestion, making timing unreliable. Situations that alter normal cytochrome P-450 function such as drug induction, (chronic ethanol use, phenytoin, and isoniazid) again render the information unreliable.⁶⁸ The use of the nomogram as the only basis for the decision to withhold NAC therapy is to be discouraged because of the uncertainty associated with this timing and the catastrophic potential if NAC is erroneously withheld (Fig. 75.5).

The main effect of NAC is to increase hepatic glutathione production. This promotes the conjugation of NAPQI and its subsequent excretion. In addition, NAC may act as an antioxidant within and outside the liver. It is most effective if given within the first 8 hours following overdose but is still effective following this, although less so. There is some evidence that NAC is effective when administered to the patient up to 72 hours following poisoning, although the mechanism of action is unclear and probably relates to antioxidant effects rather than to any effect on acetaminophen metabolism.⁶⁹ The role of NAC in established ALF from any cause is more controversial despite widespread use, but recent data have lent support to its use certainly at lower coma grades. However, the mechanism of action is unclear.^{70,71}

VIRAL HEPATITIS

Both epidemic and serum hepatitis were recognized well before the viral form was discovered. In the seminal work of Lucké and Mallory in 1946, they describe 196 patients who died of ALF following both epidemic hepatitis and serum hepatitis, related to the administration of blood products during World War II.⁵³

ALF following acute viral hepatitis is uncommon, with a reported incidence of 0.2% to 4% depending on the underlying cause.⁷² Liver failure following viral hepatitis tends to run an acute or hyperacute course with the onset of encephalopathy occurring within days or weeks of the first symptoms.⁷³

Hepatitis A is now rare in the United States and Western Europe but is still a common form of acute enterally transmitted hepatitis in the underdeveloped world where it is mainly a mild and self-limiting illness of children.^{73,74} Infection with hepatitis A carries the lowest risk of conversion to acute hepatic failure of all the hepatotropic viruses. In the West the incidence of ALF following hepatitis A appears to be higher than in the endemic areas. It occurs more commonly in adults and is more severe. Persistent infection with hepatitis A has also been reported⁷⁵ and even recurring following liver transplantation.⁷⁶ Diagnosis is made on the basis of IgM antibodies at the time of hospitalization although false-negative results can occur.⁷⁷

Hepatitis B may lead to ALF in several settings. It occurs most commonly following acute infection but can occur following an acute increase in viral replication following immunosuppressive therapy such as cancer chemotherapy or steroids as well as with coinfection with other viral agents such as delta virus. The host immune response is thought to be responsible for the severity of reaction to the virus,

Figure 75.5 Normal treatment line and high-risk treatment line for the initiation of *N*-acetylcysteine treatment based on serum acetaminophen levels and hours following ingestion. The high-risk line has been adopted as the standard and only treatment line in the UK. This is to avoid confusion and to reduce the risk of under-treatment in patients with chronically induced hepatic enzymes, such as those receiving anti-epileptic medication, chronic ethanol abusers, or smokers. If there is any doubt about the number of hours since ingestion, or if there is any suggestion of a staggered overdose or chronic over-ingestion, NAC should be administered. (Drug Safety Update September 2012, vol 6, issue 2: A1.)

subsequent clearance, and the induction of ALF. This can be seen following the withdrawal of immunosuppressive therapy when there is a very active immune response to the increased viral load. In acute infection surface antigen (HBsAg) is often negative but IgM antibodies to the viral core (HBcAb) will usually be positive. Mutations to the precore stop codon or the core promotor region of the viral genome may be associated with a higher incidence of ALF.⁷⁸ These particular genes code for HBeAg, and lack of this antigen is associated with a more profound immune response. There have been reports of a very high incidence of ALF associated with outbreaks of acute hepatitis B in the setting of intravenous drug use and chronic hepatitis C infection.⁷⁹ Lamivudine antiviral therapy for acute HBV-induced hepatitis has been tried, but because of the lack of controlled trials, it is difficult to know if it or other drugs like it help.⁸⁰

Hepatitis C, as a cause of ALF, is rare in northern Europe and the United States but has been described.⁸¹ There is a wide spectrum of clinical presentation associated with acute infection with the more florid presentation associated with a more rapid clearance rate, suggesting that the magnitude of the initial immune response is important.⁸² Liver failure associated with acute infection appears to be more common in India and the Far East.⁸³ Acute infection may contribute to decompensation in patients with preexisting liver disease, and hepatitis C seropositivity may predispose to liver failure when coinfection with another hepatotropic virus is present.⁸³

Hepatitis E is likely the most common cause of ALF worldwide and certainly for the Indian subcontinent.⁸³ In the Far East acute HBV infection is the most common cause of ALF due to the high levels of endemicity.⁸⁴

The existence of hepatitis E was inferred before serologic evidence was available by a process of exclusion. It was long assumed that most if not all epidemic enteric hepatitis was due to the A virus. When serologic markers for hepatitis A became available in the early 1980s it was apparent that the majority of waterborne epidemic hepatitis were due to other agents, producing a syndrome similar clinically to hepatitis A.⁸⁵ Hepatitis E does not produce a chronic infection and in the vast majority is a self-limiting infection that occurs most commonly in young adults, in contrast to hepatitis A, which is primarily an infection of children. The incidence of hepatitis E associated with ALF is low, with a case-related mortality rate reported at about 0.5% to 4% in the general population but with a much higher mortality rate in pregnancy, as high as 20% in the third trimester. Pregnancy itself appears to be a risk factor for ALF, with a quarter of all infected female patients reported as pregnant in one series. However, this may not be particular to hepatitis E but rather due to the high incidence of epidemic hepatitis E in a relatively immunosuppressed state and pregnant patients do not have a worse prognosis compared to nonpregnant patients with ALF due to hepatitis E.^{83,86}

Five genotypes have been described with 1 to 4 infecting humans and genotype 5 infecting only birds. Genotype 1 is the most common in Asia, with genotype 2 more common

in Africa and South America. Genotype 3 can infect both human and animals, whereas genotype 1 and 2 have been described only in humans.⁸⁷ In the West, travel to endemic areas is a risk factor, but sporadic cases are now being seen more commonly in the developed world. Some of these cases have been associated with contact with animals.⁸⁷

Seronegative hepatitis is the second most common cause of ALF worldwide in most published series. In northern Europe and the United States it comes in behind paracetamol toxicity, and in the developing world it is second to acute viral hepatitis (Figs. 75.6 and 75.7).

Seronegative hepatitis can be conveniently thought of as a single entity. In reality it is probably an amalgam of various causes that have defied definition or characterization, including acute presentations of autoimmune hepatitis, idiosyncratic drug reactions, and viruses.^{88,89} Seronegative hepatitis has a variable clinical presentation including a slow insidious onset of general malaise, jaundice, and ascites followed by progressive signs and symptoms of liver failure. At presentation the patient may be deeply jaundiced and may already have ascites and splenomegaly. It can also present with a hyperacute picture. The pattern of signs, symptoms, and organ failure is dictated by the rate of progression. In subacute seronegative hepatitis, the presenting clinical picture can be similar to that of decompensated chronic liver disease, causing occasional diagnostic difficulty. A liver biopsy is sometimes needed to differentiate between the two.

Figure 75.6 Etiology of acute liver failure in the United States 1998-2001 based on 17 centers. (From Ostapowicz G, Fontana RJ, Schiødt FV, et al: Results of a prospective study of acute liver failure at 17 tertiary care centers in the United States. *Ann Intern Med* 2002;137:947-954.)

Figure 75.7 Causes of acute liver failure in an Indian center 1989-1996. (From Khuroo MS, Kamili S: Aetiology and prognostic factors in acute liver failure in India. *J Viral Hepat* 2003;10(3):224-231.)

ACUTE PRESENTATION OF AUTOIMMUNE HEPATITIS

Autoimmune hepatitis can occur at any time of life from childhood until old age. It is more common in women with a male/female ratio of 1:3. Presentation can be asymptomatic, discovered following routine laboratory testing, or more commonly, the infection may present with jaundice and general malaise. In rare cases autoimmune hepatitis can present as ALF.⁹⁰ Unfortunately there are no serologic tests with sufficient sensitivity or specificity to make the diagnosis certain. Patterns of markers in the right clinical setting and in the absence of other causes may be useful.⁹¹ The diagnosis of autoimmune hepatitis in the setting of ALF is difficult and a degree of uncertainty often lasts. Classically there is a combination of elevated immunoglobulin levels, autoantibodies, and confirmatory histologic evidence of hepatitis in the absence of active viral markers. Elevation of autoantibodies is often seen in patients with ALF due to other causes such as drug-induced liver disease.⁹⁰ Liver failure should be assessed in the same way as for other causes, and once signs of encephalopathy become apparent, standard prognostic criteria apply. The role of steroids is unproved but should be considered in patients prior to the onset of encephalopathy. Once the patient is listed for transplantation steroid use is controversial because of increased risk of infection.

DRUG-INDUCED LIVER DISEASE

The liver is a major site for drug metabolism in the body. Metabolism of xenobiotics (a chemical which is found in an organism but which is not normally produced or expected to be present in it) takes place in a series of specialized enzyme reactions that increase the water solubility of lipophilic molecules by the incorporation of polar groups. Drug metabolism often involves a number of processes. Intermediates produced during the process are sometimes more toxic than the parent drug and can cause liver damage by a number of mechanisms.

Drug-induced liver disease may be due to a known dose-dependent toxicity, as with paracetamol. Alternatively, unpredictable, rare, idiosyncratic reactions can occur with any drug with a frequency of about 1 in 1000 to 1 in 100,000 patient prescriptions.⁶⁸ Drug-induced liver failure can mimic all forms of acute and chronic liver disease. However, the predominant clinical presentation consists of either acute hepatitis or cholestatic liver disease. The former has a reported mortality rate of 10% irrespective of the drug.

The patterns of injury associated with these idiosyncratic reactions relate to the mechanism of damage and the cells involved.⁹² Many patterns have been described but it is massive hepatic necrosis that most often presents as ALF. Liver failure associated with severe cholestasis and veno-occlusive disease is also seen.⁹²

Liver injury usually is seen within 6 months following the initiation of therapy. Even if the diagnosis of drug-induced liver failure is considered, a search for other possible causes should be performed. Although any drug is capable of inducing liver injury, more common causes include herbal remedies and recreationally used drugs such as "ecstasy" and cocaine. If suspected, a comprehensive history with a timetable of drug initiation should be constructed. Management includes stopping the offending drug and supportive

Table 75.1 Idiosyncratic Drug Reactions and Effects on Cells

Type of Reaction	Effect on Cells	Examples of Drugs
Hepatocellular	Direct effect or production by enzyme-drug adduct leads to cell dysfunction, membrane dysfunction, cytotoxic T-cell response	Isoniazid, trazodone, diclofenac, nefazodone, venlafaxine, lovastatin
Cholestasis	Injury to canalicular membrane and transporters	Chlorpromazine, estrogen, erythromycin and its derivatives
Immunoallergic	Enzyme-drug adducts on cell surface induce IgE response	Halothane, phenytoin, sulfamethoxazole
Granulomatous	Macrophages, lymphocytes infiltrate hepatic lobule	Diltiazem, sulfa drugs, quinidine
Microvesicular fat	Altered mitochondrial respiration, beta-oxidation leads to lactic acidosis and triglyceride accumulation	Didanosine, tetracycline, acetylsalicylic acid, valproic acid
Steatohepatitis	Multifactorial	Amiodarone, tamoxifen
Autoimmune	Cytotoxic lymphocyte response directed at hepatocyte membrane components	Nitrofurantoin, methyl dopa, lovastatin, minocycline
Fibrosis	Activation of stellate cells	Methotrexate, excess vitamin A
Vascular collapse	Causes ischemic or hypoxic injury	Nicotinic acid, cocaine, methylenedioxymethamphetamine
Oncogenesis	Encourages tumor formation	Oral contraceptives, androgens
Mixed	Cytoplasmic and canalicular injury, direct damage to bile ducts	Amoxicillin-clavulanate, carbamazepine, herbs, cyclosporine, methimazole, troglitazone

IgE, immunoglobulin E.

From Lee WM: Drug-induced hepatotoxicity. *N Engl J Med* 2003;349(5):474-485.

care. Transplantation should be considered once liver failure occurs as the outcome from drug-induced liver failure, other than that induced by paracetamol, can be poor.⁹³ Presentation profiles for various drugs causing ALF are shown in [Table 75.1](#).⁶⁸

PREGNANCY-INDUCED LIVER DISEASE

In general, pregnancy-associated liver failure has the best prognosis when compared to all other causes of ALF, and prompt recovery can be expected with delivery of the fetus in most cases, if recognized early enough. Pregnancy-associated liver failure can present in several ways including the syndromes of preeclampsia and the HELLP syndrome (hemolysis, elevated liver function tests, and low platelets), liver rupture, and acute fatty liver of pregnancy.⁹⁴ Any cause of ALF can occur during pregnancy, and in particular viral hepatitis can be particularly fulminant in its course. This is especially true for hepatitis E and herpes simplex virus infection.

Although originally thought to be a variant of preeclampsia there is evidence that HELLP syndrome may be a separate entity and in fact more related to acute fatty liver of pregnancy.⁹⁵ Both HELLP and preeclampsia appear to be related to an endothelial injury, possibly immunologically initiated with activation of the coagulation and complement cascades and an imbalance of prostaglandin and thromboxane resulting in increased vascular tone, microangiopathic hemolytic anemia, and vascular thrombosis.⁹⁶ About 2% to 12% of severe preeclampsia is complicated by HELLP.⁹⁴ HELLP is thought to occur in approximately 1 in every 1000 live deliveries and patients usually present in the third trimester with nonspecific signs often seen in preeclampsia

such as weight gain due to edema and hypertension. In addition, right upper quadrant pain accompanied by nausea and vomiting is commonly seen. Laboratory abnormalities include hyperbilirubinemia due to liver dysfunction and evidence of hemolysis. Transaminases are modestly raised and the platelet count is usually less than 100,000/ μ L. Liver biopsy, while commonly normal in preeclampsia, shows specific changes of periportal necrosis and fibrin microthrombi. Microvascular steatosis may also be present.⁹⁶ The liver failure associated with HELLP is manifest as a prolonged prothrombin time and ascites. Renal failure is common. Maternal mortality rate is low but fetal mortality rate has been reported to be between 20% and 60%, although some reports suggest this is lower at 7% and associated with twin pregnancies.^{96,98} The treatment of choice is delivery of the baby. Conservative therapy is associated with an increase in both maternal and fetal complications.

Spontaneous rupture of the liver can occur in the setting of both preeclampsia and the HELLP syndrome, although it can occur de novo. It often presents with sudden onset of right upper quadrant pain accompanied by signs of hypovolemia or shock and is more common in multiparous women.⁹⁶ Spontaneous rupture of the liver has high maternal and fetal mortality rates. Its pathogenesis is unclear but it appears that periportal hemorrhage associated with HELLP syndrome may occur close to the capsule, resulting in lifting and bleeding into the potential space. These areas of the capsule then coalesce and rupture. Management of this devastating complication includes prompt delivery of the fetus, local surgical control with packs, and aggressive management of the accompanying coagulopathy. Embolization of any feeding vessels in the liver may be of utility if

such skills are available. Hepatectomy followed by liver transplantation can be lifesaving and has been performed.

Acute fatty liver of pregnancy (AFLP) occurs during the third trimester of pregnancy and should be considered in any patient exhibiting signs of liver dysfunction. It is uncommon with an incidence of approximately 1 in 6659 live births.⁹⁹ If left untreated, maternal and fetal mortality rates are high. The treatment of choice is delivery and prompt recovery can then be expected. There is usually a prodromal illness over a couple of weeks with nonspecific symptoms progressing to jaundice and encephalopathy. Symptoms and signs of preeclampsia or HELLP syndrome are seen in a third of cases and there is some evidence of a common origin due to a fetal fatty acid metabolism disorder.⁹⁵ Diagnosis is critical and it should be differentiated from viral hepatitis or hepatic failure due to other causes. Liver biopsy can aid in the diagnosis and can be performed via the jugular route if coagulopathy precludes the conventional approach. Characteristic zone 3 microvesicular steatosis is seen. Delivery is the best treatment if diagnosed early. Characteristic features include normoblasts on blood smears and high serum urate. Bleeding can be a major problem during operative delivery. On occasion transplantation may be the only viable option. Triggers for transplantation in pregnancy-induced liver failure are not well defined and the Kings College Criteria perform poorly. Arterial lactate in the setting of encephalopathy appears to be the best predictor.⁹⁸

WILSON'S DISEASE

Wilson's disease is a rare autosomal recessive disorder resulting from copper toxicity with primarily brain and liver manifestation. It usually presents in the second or third decade of life, although it can present from early childhood until late middle age.¹⁰⁰ The disease can present with predominantly liver or neurologic symptoms. Neurologic symptoms relate to the distribution of copper to the basal ganglia and result in movement disorders. Patients presenting with liver disease may present with an active hepatitis, established cirrhosis, or ALF. Other signs such as Kayser-Fleischer rings are associated but not pathognomonic for Wilson's disease. These greenish brown rings in the cornea result from the deposition of copper.

ALF due to Wilson's disease can present at any age but more commonly presents in the early 20s. High urinary copper excretion is possibly the most predictable laboratory finding, although the patient may be anuric on presentation. A low serum ceruloplasmin is an additional indicator but again is unreliable in ALF. A high serum bilirubin in combination with modest elevations of transaminases and alkaline phosphatase is often seen, as is intravascular hemolysis, contributing to the raised bilirubin level. Patients with severe liver failure due to Wilson's disease have an almost 100% mortality rate without liver transplantation, which should be considered as soon as the diagnosis is made.¹⁰⁰ There is debate as to whether liver failure secondary to Wilson's disease is truly ALF, as cirrhosis is invariably present on liver biopsy at the time of presentation. Nevertheless, many patients present acutely and the presentation is often catastrophic. In this sense the timing of the onset and the lack of previous symptoms place fulminant Wilson's disease in the ALF group. In an uncontrolled series the

administration of D-penicillamine before the onset of encephalopathy was associated with survival.¹⁰¹

NEOPLASTIC INFILTRATION

Poorly differentiated solid tumors such as breast and lung and hematologic malignancies can sometimes present with a syndrome of liver failure. There is often diagnostic delay and difficulty.

The syndrome can be considered as part of the hypoxic hepatitis group as zone 3 necrosis is often seen. The metabolic demand of the neoplastic cells and congestion within the liver sinusoids results in infarction of hepatocytes. Hepatosplenomegaly and a raised alkaline phosphatase are often present. Other stigmata including palpable lymphadenopathy and marrow or peripheral blood film changes may be present. Imaging may be diagnostic, especially with massive hepatomegaly, but biopsy may be required.¹⁰²

BUDD-CHIARI SYNDROME

ALF secondary to Budd-Chiari syndrome is usually fatal without transplantation. The syndrome is defined as outflow obstruction to the hepatic veins and the underlying pathogenesis is thrombosis in the majority but tumor invasion or vascular membrane obstruction may be the cause. This is a rare disorder that occurs predominantly in young adults and affects more women than men. Overall, the 5-year survival rate varies from 50% to 80% in different series.¹⁰³ The vast majority of patients with the syndrome have at least one predisposing clotting abnormality, either congenital or acquired, such as a malignancy, myeloproliferative disorders, protein C or S deficiency, polycythemia rubra vera, lupus anticoagulant, antithrombin III deficiency, antiphospholipid syndrome, etc.¹⁰⁴ The fulminant form of the syndrome in which the patient develops encephalopathy within 8 weeks of the onset of symptoms is rare, and it is much more common for Budd-Chiari syndrome to present in a subacute form over a 3- or 4-month period, characterized by ascites, abdominal pain and hepatomegaly, jaundice, coagulopathy, and raised AST and alkaline phosphatase. Others present with signs of portal hypertension, including refractory ascites and variceal bleeding, and relatively intact hepatocellular function. The diagnosis is made with the combination of clinical presentation and imaging, including Doppler ultrasound studies of the hepatic vessels, plus or minus liver histologic examination, usually via the jugular route because of coagulopathy. Management of the syndrome depends on the manner in which it presents and the underlying cause. Medical management of the syndrome involves the use of anticoagulants and diuretics in an attempt to control ascites. Thrombolysis can be attempted in selected patients with recent onset disease.¹⁰⁵ In patients in whom there is progression to signs and symptoms of liver cell failure some sort of portosystemic shunting procedure may reduce symptoms and prevent progression of the disease, allowing time for collateral vessels to develop. Transjugular intrahepatic portosystemic shunt (TIPSS) is most often attempted unless there is evidence of a hypertrophied caudate lobe and inferior vena cava compression, making mesoatrial shunting a better option. In patients with signs of liver failure care must be used when considering a TIPSS procedure, as this can precipitate decompensation and rapid progression to ALF.¹⁰⁶ Liver transplantation is

ultimately the only option in many patients in which there is a failure of medical and shunt therapy as well as in the fulminant presentation of the syndrome.¹⁰⁷ Anticoagulation is usually necessary in the immediate postoperative period.

VENO-OCCLUSIVE DISEASE OF THE LIVER

Veno-occlusive disease (VOD) of the liver is a nonthrombotic obstruction of the sinusoids, which may extend to the central veins, in the absence of thrombosis or other underlying disorder of the hepatic veins.¹⁰⁸ As a result of a toxic challenge there is acute damage to the endothelial cells, followed by their detachment and their embolization in the central area of the lobule, where they cause a postsinusoidal outflow block.¹⁰⁸ The most common cause is myeloablative chemotherapy induction regimens in preparation for bone marrow transplantation (BMT), being seen in up to 54% in some older series.¹⁰⁹ Other toxins are known to cause it and it was first described in children following the ingestion of herbal teas in South Africa and it represents a nonspecific response to certain noxious stimuli. Particular induction regimens such as high-dose cyclophosphamide and total body irradiation are implicated in the pathogenesis. The more aggressive induction regimens appear to result in a higher incidence of VOD. Recent reduction in incidence may be due to a reduction in the use of myeloablative regimens and better monitoring of plasma drug concentrations.¹¹⁰ The symptoms of VOD usually occur within 2 weeks of BMT. The development of jaundice, hepatomegaly, abdominal pain, and encephalopathy in the setting of recent BMT strongly suggests the diagnosis. Severe cases are characterized by evidence of hepatocellular necrosis and a high AST concentration. In 25% of cases, which are characterized as severe, the syndrome is progressive, leading to ALF.¹¹¹ Treatment options in these patients are limited as the outcome is poor with medical management or liver transplantation, although there is hope that newer therapies such as defibrotide (a deoxyribonucleic acid derivative anticoagulant with multiple modes of action), if initiated early before the onset of multiple organ failure, may improve the outlook. In addition, the prophylactic use has been tried in several noncontrolled reports.¹⁰⁸

HYPOXIC (ISCHEMIC) HEPATITIS

“Shock liver,” “ischemic hepatitis,” or more recently hypoxic hepatitis is the most common cause of significant rise in serum aminotransferase (S-AT) seen in hospitalized patients (Fig. 75.8).

There is often an underlying chronic reduction in oxygen delivery to the liver due to comorbid disease states such as congestive cardiac failure or chronic respiratory failure. There is then a subsequent sudden acute drop in oxygen delivery due to a decrease in cardiac output or further hypoxia.

Diagnostically, there are three conditions that should be met: the appropriate clinical setting of circulatory, cardiac, or respiratory failure with a massive rise in S-AT and the exclusion of other causes of massive hepatic necrosis such as viral or drug-induced liver failure.¹⁰²

In patients with chronic congestive heart failure (CCHF), liver congestion is common. This is usually manifest as mild abnormalities of liver function tests, a prolonged

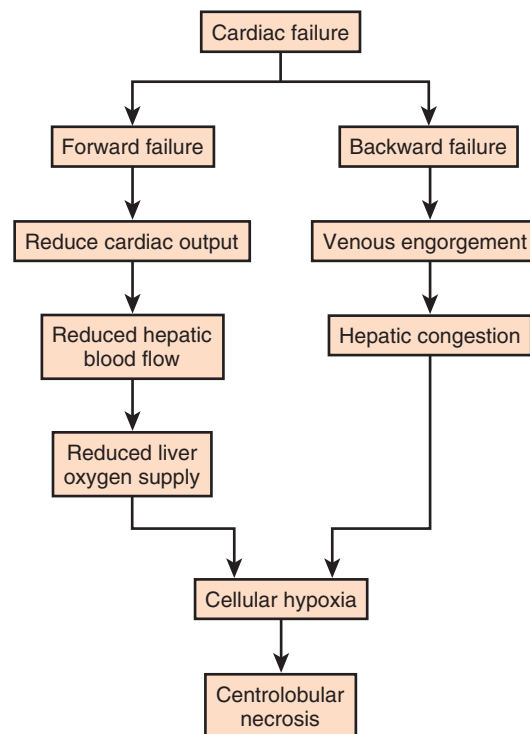

Figure 75.8 The most common cause of hypoxic hepatitis results from a combination of liver congestion due to chronic cardiac failure and an acute drop in cardiac output causing liver ischemia.

prothrombin time, and mild ascites in some. Hepatic congestion is usually clinically unapparent unless jaundice is present, which can occur following multiple bouts of CCHF. Chronic congestion can lead to fibrosis and ultimately cirrhosis in some patients. Acute rises in serum transaminase and prolongation in prothrombin time, representing acute hepatic necrosis, most commonly develop in patients with CCHF when there is a sudden drop in cardiac output due to an event such as an arrhythmia or myocardial infarction. It is relatively uncommon for the liver to become involved during shock states because of the huge redundancy in blood supply and the ability of the portal system to compensate for any reduction in hepatic arterial flow. If, however, portal flow is already compromised due to passive congestion, then an acute drop in hepatic blood flow can result in ischemia. It is uncommon for hypoxic hepatitis to occur without a recognizable precipitant, but it can occur due to a silent myocardial infarction or arrhythmia, for example. It can occur before the diagnosis of CCHF has been made or be the primary diagnostic event in a younger patient with a cardiomyopathy. Clinically, severe ischemic hepatitis becomes apparent between 24 and 48 hours following an event and is manifest as huge rises in S-AT (up to 10-20 times normal). There is prolongation of the prothrombin time, encephalopathy, hypoglycemia, jaundice, and renal failure. The syndrome is usually self-limiting once the hemodynamic disturbance has receded, and there is a rapid fall in serum transaminases (usually 50% in the first 72 hours).¹¹² Occasionally, progressive liver cellular failure leads rapidly to death. Management should be aimed at investigating and supporting the underlying cause.

HEAT STROKE

Liver failure in the setting of heat stroke can be considered to be part of the hypoxic hepatitis group of causes. The argument for its inclusion here is the zone 3 necrosis seen in the liver following autopsy in patients who survive long enough for a reperfusion injury to occur.¹⁰² The pathophysiology is complex but is probably related to dehydration and cardiovascular collapse plus increased oxygen demand and acute cardiac failure.¹⁰² Exertional heat stroke may occur in new recruits to the army or police force engaging in physical initiation programs. It can also occur in unacclimatized athletes in hot conditions or with drug overdoses such as cocaine and hyperpyrexia syndrome such as those induced by MDMA (methylenedioxy-*N*-methylamphetamine). It is a potentially devastating syndrome that can lead to multiple organ failure and death. It ranges from mild involvement to ALF and is seen to develop during the first few days following the event. Management is supportive and the majority improves over a period of days to weeks. Liver transplantation has been used in severe cases but the outcome is poor owing to coincident organ failure.¹¹³

MUSHROOM POISONING

There are many types of poisonous fungi in the world that are responsible for a variety of disorders that can be classified according to the type of poisoning and the timing of onset.¹¹⁴ There are a number of fungi associated with the induction of liver failure following ingestion. Of these, the most common and most deadly are of the genus *Amanita*. *Amanita* associated hepatotoxicity follows a triphasic response after ingestion. The first is a self-limiting, nonspecific gastrointestinal upset that occurs within the first 6 to 24 hours. Nausea and vomiting, abdominal cramps, and diarrhea are often seen and it can mimic food poisoning. This is followed by a period of recovery and a few days later by progressive liver failure.

Management is essentially supportive, although many specific therapies have been tried in the treatment of *Amanita* toxicity such as high-dose penicillin, silibinin, cimetidine, and NAC, but none has been shown to improve outcome. Liver transplantation should be considered for patients with severe liver failure and standard criteria apply.¹¹⁴

CLINICAL COURSE

HISTORY AND PHYSICAL EXAMINATION

The presentation and clinical course of ALF depends on its cause and the rate of progression of the syndrome. This varies widely from admission via an emergency department following a paracetamol overdose or acute viral hepatitis versus admission from a hepatology outpatient department in a patient with progressive jaundice and ascites. Owing to its relative rarity the diagnosis can often be missed during initial contact and this delay may detrimentally influence the outcome.

The history will initially focus on the rate of progression of the illness and any clues to the cause. The first symptoms are often the onset of jaundice (typically noticed by a relative). Any history of foreign travel or high-risk behavioral activity (intravenous drug use or unprotected sex) associated with the contraction of viral hepatitis should be

investigated. A thorough drug history should be taken for prescribed and recreational drug use for the preceding 6 to 10 weeks. Drug therapy or recreational use that can induce or inhibit hepatic enzymes should be noted. If the patient is unable to provide this information, the relatives and the patient's primary care physician should be contacted for help.

The history may be self-evident in the case of paracetamol hepatotoxicity, especially if the patient is self-presenting following deliberate self-harm. However, therapeutic misadventure, which is a relatively common cause of hepatotoxicity, especially in the United States, may not be obvious unless considered by the physician.¹¹⁵ Any patient presenting with coma should have a drug screen (including paracetamol).

Subacute liver failure has, by definition, a more insidious onset. Jaundice is often preceded by nonspecific symptoms of fatigue and general malaise. Abnormal liver enzymes will often be revealed during the initial workup. Subsequent investigations will include viral, iron, copper and genetic studies and, in addition, attempt to rule out decompensation of chronic liver disease as a cause the current symptoms and signs. Liver biopsy may be considered in subacute liver failure (Fig. 75.9).

INITIAL RESUSCITATION AND EMERGENCY CARE

Patients presenting with acute or hyperacute liver failure tend to follow a similar course irrespective of cause. Initial therapy and emergency care will be dictated by the condition of the patient at presentation. Liver failure is a multi-system disease and can progress very rapidly to multiple organ failure.

Patients presenting with rapidly progressive hepatic encephalopathy via the emergency care system will often be intubated and ventilated at the time of or shortly after admission. The emergency physicians will often perform a head computed tomography (CT) scan because of diagnostic uncertainty.

The symptoms and signs of hepatic encephalopathy in ALF are subjectively different from those seen in decompensated chronic liver disease or in patients with stable chronic encephalopathy. Agitation and aggressive behavior are more common in ALF. This may be based on an increased turnover of the excitatory neurotransmitter glutamate in ALF associated with an acute increase in cerebral ammonia uptake.¹¹⁶

The West Haven criteria, designed to assess coma grade in patients with cirrhosis, are often applied to patients with ALF and are useful because of familiarity.¹¹⁷ However, once the patient becomes unconscious at grade IV encephalopathy, the scale does not provide any further information and is too crude to provide a clinically useful description of the level of consciousness. The Glasgow Coma Scale score, while not assessed specifically in this setting, is useful in relating clinical information to others.¹¹⁸ Encephalopathy grade can progress very quickly, especially with hyperacute presentation. Intubation and sedation are recommended once grade III encephalopathy is achieved because of the attendant risks to airway and possibilities of raised intracranial pressure, discussed later. Figure 75.10 describes encephalopathy grade and Glasgow Coma Scale score.

Early contact with a regional liver center should be made in any patient with signs of acute severe liver dysfunction as

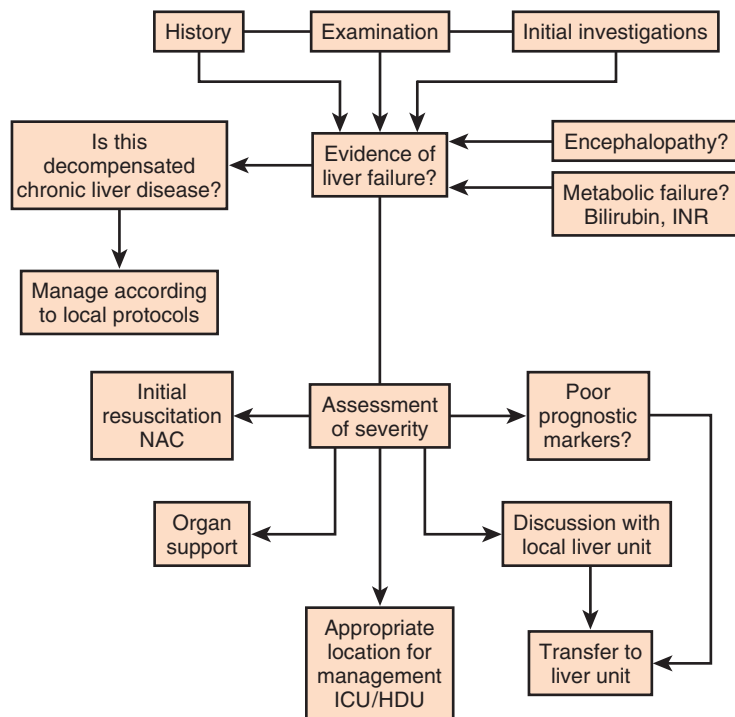

Figure 75.9 Initial management of a patient presenting with liver failure. HDU, high dependency unit; ICU, intensive care unit; INR, international normalized ratio; NAC, *N*-acetylcysteine.

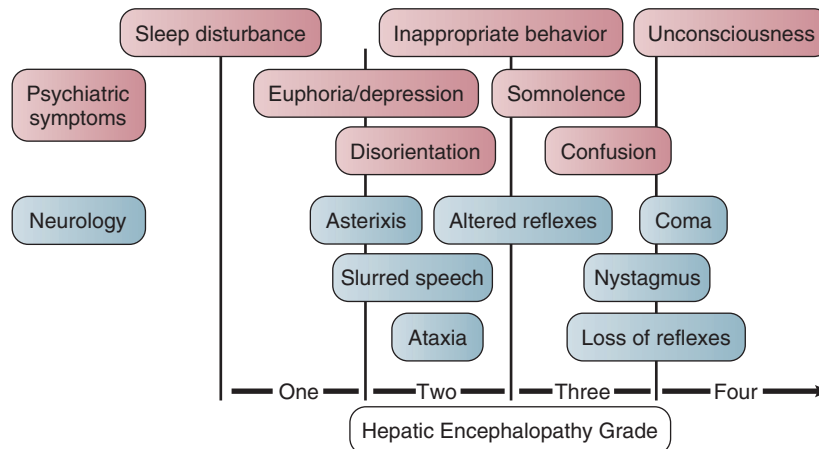

Figure 75.10 Hepatic encephalopathy grade in acute liver failure.

serial blood results and clinical signs can be relayed to the center over the phone. POD patients can often be managed over the phone but plans for transfer can be made well in advance, if necessary. As liver failure progresses over the next several days, a number of organ systems may become affected.

Following the safe and appropriate management of airway and breathing, focus can be directed to the correction of any circulatory dysfunction. Patients with ALF can progress rapidly to circulatory shock. The circulatory changes associated with ALF are predictable, usually associated with systemic vasodilatation and relative hypovolemia. This can be profound and require significant volume resuscitation. It is easy to underestimate the amount of fluid required in the early stages of ALF and the use of prognostic markers is

unreliable before adequate circulatory function is restored. Monitoring at this stage should include a central venous catheter and direct arterial access for both blood pressure monitoring and for repeated blood tests. Care must be given to serum electrolytes because they often become deranged during this initial period. In particular, hyponatremia and hypophosphatemia are common.¹¹⁹⁻¹²¹ This may be due to excess quantities of hypotonic fluid administration. A typical flowsheet of investigations of a patient presenting with paracetamol poisoning from a referring hospital is shown in [Box 75.2](#).

Regardless of cause, patients with significant liver damage or signs of secondary organ dysfunction should be managed within the ICU. The speed at which patients deteriorate can be very rapid and it is not uncommon for hepatic

Box 75.2 Acetaminophen Overdose Case Example: Laboratory Data

A 20-year-old woman, an intravenous drug user, took a 250-tablet overdose (500 mg of acetaminophen) the day before presentation at the hospital emergency department. She received *N*-acetylcysteine alanine transaminase 25 hours after the ingestion. The patient was then transferred and listed for transplantation.

Dates	7/10/2003	8/10/2003 AM	8/10/2003 PM	9/10/2003 AM

Table 75.2 Initial Investigation and Common Findings

Laboratory Test	Finding(s)
Complete blood count	Platelets often low
Urea and electrolytes	Serum sodium often low, especially in paracetamol hepatotoxicity Urea often low because of reduced production Serum creatinine is useful prognostic marker
Liver enzymes	Serum AST/ALT variable, very high in paracetamol toxicity Bilirubin is prognostic marker in nonparacetamol liver failure Also can be high in Wilson's disease from hemolysis
Phosphate	Often low, especially in paracetamol toxicity High level indicative of poor prognosis; suggests lack of regeneration
Magnesium	Often low
Prothrombin time, international normalized ratio (INR)	Very sensitive indicator of liver function Has prognostic significance in all forms of acute liver failure May improve with vitamin K in deficiency states
Viral serology for all known hepatotropic viruses	
Urinary copper, plasma ceruloplasmin if Wilson's disease is suspected	Ceruloplasmin level often very low but can be normal Urine copper usually high
Arterial ammonia	Has some prognostic value and may be an indicator of cerebral edema in patients at risk
Arterial whole blood lactate	Very sensitive marker for liver function, particularly in paracetamol toxicity High level indicative of poor prognosis
Serum glucose	Hypoglycemia common
β -Human chorionic gonadotropin in women	Unwanted pregnancy can be a precipitant of deliberate self-harm

AST/ALT, aspartate transaminase/alanine transaminase.

encephalopathy to progress from grade 0 to grade IV over several hours.

For prognostic reasons it is important not to avoid correcting any biochemical coagulopathy at this stage if possible. Despite quite significant prolongation of prothrombin time, bleeding from line sites is uncommon in the initial stages of ALF. In fact, there is evidence that the patients are prothrombotic in vivo.¹²²

INVESTIGATION IN A PATIENT WITH SUSPECTED ACUTE LIVER FAILURE

Initial investigations provide a baseline from which important diagnostic and prognostic information is taken. Serial

blood test measurements should be performed as severity and prognosis are assessed over time from initial presentation (Table 75.2). Depending on the manner and speed of presentation, a complete blood count, clotting tests, liver function tests, arterial blood gas measurements, and ammonia levels should be performed twice daily, if not more often, in the early stages to assess progression of the illness. A liver ultrasound scan to assess liver size and blood supply should be performed.

TRANSFER CRITERIA GUIDE

ALF is a sporadic syndrome with a case incidence of about 2000 per year in the United States.¹²³ Management is

complex and liver transplantation is the only effective therapy in severe cases. Transfer to a unit with experience in the management of these patients, preferably one with a liver transplant program, will provide optimal care. It is often difficult to decide when or whether to transfer a patient with acute liver dysfunction, and this decision will vary according to cause and presentation. The best described clinical course is that following severe paracetamol poisoning after a deliberate overdose.⁵² Staggered overdose and therapeutic misadventure are less predictable in their clinical course but often have a poor outcome and can be considered a poor prognostic risk factor.¹²⁴

The following criteria for transfer are based on expert opinion and have not been subjected to rigorous study and err on the side of caution⁷² (Fig. 75.11):

- In patients with a subacute presentation it is better to transfer patients before they have progressed to grade II encephalopathy because of the additional complications associated with transferring ventilated patients.
- Patients with acute or hyperacute liver failure showing signs of early encephalopathy should be intubated and ventilated prior to transfer. This can occasionally result in disagreement between referring hospitals and receiving liver units on how the transfer should be managed. There are many anecdotal stories from liver units around the world describing patients who become unmanageable during transfer in planes, helicopters, and road ambulances resulting in injury to patients and staff.
- Heroic transfers are almost always inappropriate. Patients should not be considered for transfer if they are on rapidly accelerating inotropic support, have severe hypoxemia, or already have fixed dilated pupils. There is little point a patient dying in an ambulance.

MANAGEMENT

SUPPORTIVE CARE

Airway and Ventilation

Patients with ALF who reach grade II or III encephalopathy require intubation and ventilation to provide safe management in the setting of increasing agitation, protection of the airway from stomach contents, or transfer from peripheral hospitals. In patients with severe liver failure it can be expected that encephalopathy grade will progress, and so waiting until some predefined stage before intubation often delays adequate resuscitation and monitoring.

Controlled ventilation to a normal Paco_2 is recommended at this stage. The use of hyperventilation is not indicated without further monitoring.^{125,126}

Circulation

The circulatory changes associated with ALF can be profound.¹²⁷ The pathologic basis for this are incompletely understood, but similar in many ways to changes observed in patients with a systemic inflammatory response due to sepsis or trauma. The pattern observed depends on the cause and the rate of onset of the syndrome. In hyperacute liver failure due to paracetamol overdose, patients can develop fulminant peripheral cardiovascular collapse that can be an early mode of death.¹²⁸ Others with a more subacute onset can develop peripheral vascular changes similar to those with decompensated chronic liver disease and hepatorenal failure.

Fluid resuscitation should be commenced as soon as possible after presentation and should be directed by invasive monitoring. The type of fluid used for resuscitation has not been subjected to controlled trials in this setting but large volumes of hypotonic fluids should be avoided as this

Referral to specialist unit after paracetamol ingestion. Any of these criteria should prompt referral.

may contribute to cerebral swelling seen in this group, and it has been shown that hypertonic saline infusion reduces the incidence of intracranial hypertension in patients with ALF.¹¹⁹

If following adequate fluid resuscitation mean arterial pressure remains less than 65 mm Hg, a vasopressor should be commenced. Norepinephrine is the vasopressor of choice as it induces vasoconstriction without the induction of lactate production as often seen with the use of epinephrine, although epinephrine has been used in this setting successfully.

Vasopressin and its longer acting analog terlipressin have been used as vasopressors in septic and cardiogenic shock.^{129,130} Terlipressin results in profound systemic vasoconstriction and, if used inappropriately, has the potential to reduce cardiac output and hence oxygen delivery. It has been shown to increase intracranial hypertension in ALF due to an increase in cerebral blood volume because of the breakdown in cerebrovascular autoregulation.¹³¹ However, the data are mixed and a more recent study suggests that terlipressin may be a useful adjunct to norepinephrine in ALF.¹³² Because of this uncertainty, monitoring of ICP should be considered if it is used.

The majority of patients presenting with ALF are young adults, and as a result, comorbid cardiac dysfunction is usually absent. Cardiac depression has been reported in association with POD.¹²⁸ On occasion cardiac disease can present as ALF in the case of ischemic hepatitis.

Relative adrenal insufficiency has been shown to occur in patients with septic shock and in patients with decompensated chronic liver disease and ALF.^{44,133-135} The use of stress doses of corticosteroids in ALF has been shown to reduce norepinephrine requirements in patients with ALF.¹³⁶ The effect on outcome is uncertain, though.

Renal Support

Renal failure is common in ALF with a reported incidence of up to 70%.¹³⁷ Paracetamol causes direct renal tubular dysfunction, possibly by affecting membrane protein function and occasionally renal failure is the predominant organ affected.^{138,139} As a result, renal failure can be expected in this setting. Although it is most commonly associated with POD, the incidence in other causes, such as Wilson's disease due to the direct toxic effects of copper, is also high but it is less prominent in ALF due to viral hepatitis or seronegative hepatitis.

There remains debate regarding the cause, pathology, and definition of renal dysfunction in critical illness despite a huge amount of effort.¹⁴⁰ The term *acute tubular necrosis* is inadequate in the setting of critical illness when it fails to describe the full spectrum of renal dysfunction. This is even truer in the setting of ALF. In addition, the use of *hepatorenal syndrome* in ALF is also inappropriate because this term does not adequately describe the often rapid clinical deterioration. This is not to say that altered systemic and renal hemodynamics do not contribute to the pathophysiology of renal failure as they do in critical illness in general. In the subacute presentation of this syndrome early renal dysfunction can be similar in presentation to that seen in end-stage chronic liver disease with sodium and water retention in the absence of intrinsic renal damage.¹⁴¹

Management of renal failure is essentially the same as in ALF and other forms of multiple organ failure and consists of maintenance of intravascular volume, cardiac output, and mean arterial pressure.^{123,142}

Extracorporeal renal support is necessary in most patients with ALF at some time. Continuous venovenous hemofiltration (CVVH) is the most efficient and safest method for renal support and should be started early.¹⁴³ Indications for the early use of renal support are not just limited to oliguria. CVVH has been shown to improve hemodynamic stability in patients with critical illness and has been used as salvage therapy in patients on high-dose vasopressor.¹⁴⁴ High-volume hemofiltration (4000 mL/hour ultrafiltrate exchange) has been studied in ALF and has been shown to reduce serum lactate, base deficit, and norepinephrine requirements when compared to historical control subjects.¹⁴⁵ Evidence for survival benefit for high-dose renal replacement therapy in critical illness is lacking, however, and recent high-quality studies suggest that there is a ceiling of dose, above which there is no additional survival benefit.^{146,147}

Patients with liver failure do not tolerate the lactate load associated with lactate-buffered replacement fluid during CVVH. In fact, the rapid infusion of lactate can induce a systemic acidosis in this setting.¹⁴⁸ Also, the infusion of large quantities of lactate-containing fluid reduces the utility of serum lactate as one of the most important prognostic indicators.¹⁴⁹ As a consequence, the use of bicarbonate hemofiltration is recommended.¹⁵⁰

CVVH can often be performed successfully without anticoagulation in ALF. If required, a loading dose of 2000 units of heparin and thereafter 500 to 1000 units an hour, depending on the activated clotting time, can be used if needed to allow CVVH. If bleeding is a problem or there is severe thrombocytopenia, epoprostenol should be instituted (2.5-5 ng/kg/minute) either alone or in association with low-dose heparin (100 units/hour). Blood flow rates of 200 mL/minute and above will help with filter life.

INTRACRANIAL HYPERTENSION

Etiology

The hallmark of liver failure is the development of hepatic encephalopathy, which with severe liver failure progresses to deep coma. In addition to the progressive coma, early reports of patients with signs of raised ICP were noted in the literature.¹⁵¹ What is less clear is whether they possess a common cause. Certainly patients with subacute liver failure can develop a deep coma without signs of cerebral edema, but patients with signs of intracranial hypertension (ICH) always develop high-grade encephalopathy prior to this.

Cerebral edema was noted and commented on in the seminal clinicopathologic review of servicemen presenting with fulminant epidemic hepatitis during the East Asian campaign of the Second World War.⁵³ However, the recognition that cerebral edema was a distinct clinical entity and cause of death associated with ALF did not become clear until much later.^{151,152}

The recognition that brain swelling is an important component of ALF is now well established. Management strategies place the risk of ICH at the forefront of care, and prophylactic therapy, monitoring, and treatment are widely debated in the literature.^{153,154} The incidence of cerebral

edema in ALF is not completely clear and is dependent on the cause of liver failure, the severity, and the rate of onset. It is important to distinguish between ICH and cerebral edema. The former requires the measurement of pressure within the cranial vault and results in brain ischemia and signs of tentorial herniation. The latter is difficult to define clinically and depends on how hard you look. CT and post-mortem studies have suggested an incidence of between 50% and 80% of those with high-grade encephalopathy.^{151,155} The pathologic changes of cerebral edema and ICH in ALF are not completely understood, but in recent years progress has been made in understanding the processes involved.¹⁵⁶

An increase in cerebral blood flow may induce ICH by a number of mechanisms and induce further cerebral swelling. This could occur due to an increased flux of potentially toxic metabolites such as ammonia or by an increase in cerebral water content because of an increase in cerebrovascular hydrostatic pressure. The blood-brain barrier has been considered to remain intact in ALF but recent evidence suggests that there is some impairment, although the degree to which this contributes to cerebral swelling is still being debated.^{161,167}

Cerebrovascular autoregulation is lost in ALF.^{165,168} The cause is unknown but a gradual cerebral vasoparesis concurs with clinical observation. Autoregulation can be restored by hyperventilation and mild hypothermia but not by the use of indomethacin.¹⁶⁹ It has been suggested that the increase in astrocyte glutamine plays a role in this gradual vasoparesis and loss of autoregulation by the induction of local nitric oxide or carbon monoxide.¹⁵⁶ It is relatively common to find a patient with a high ICP and jugular venous oxygen saturation above 80%. This suggests a state of luxury perfusion (unregulated blood supply in excess of demand) in which an increase in cerebral blood volume in an already swollen brain accounts for the associated increase in ICP.¹⁷⁰

Management

In the management of ICH in ALF it is important to target those at risk. The development of ICH sets the management of ALF apart from other forms of critical illness and it remains a leading cause of death despite advances in the understanding of the etiology ALF and management of ALF patients.^{172,173} Monitoring the pressure within the cranial vault is difficult and invasive. Despite investigation, a reliable noninvasive method for the evaluation of cerebral blood flow, cerebral oxygenation, and ICP remains elusive.¹⁷⁴

There are important points that need to be considered when managing a patient with ALF and possible raised ICP:

- Prediction of patients at risk of ICH
- How to monitor the brain
- Prophylactic management
- Treatment of established ICH

Predicting Intracranial Hypertension

In ALF the development of cerebral edema is seen in patients with the shortest time between the development of jaundice and the onset of encephalopathy.⁵² A fulminating presentation, lack of time for cerebral adaptation, and systemic burden of a necrotic liver appear to be the likely reasons. Patients with paracetamol toxicity make up the largest number in this group. Other causes can fall into the

hyperacute group including patients with ALF due to hepatotropic viruses, particularly HBV. In contrast, patients with subacute liver failure have a smaller risk.

It has been suggested that the incidence of ICH following paracetamol toxicity has fallen since the mid-1980s.¹⁷⁵ However, it still represents a significant complication in this setting. Recent work from King's College Hospital in London suggests an incidence of 20% to 30% in all patients with ALF. Data from our own unit suggest that ICH is implicated in the death of 25% of all patients with ALF and 35% of those following paracetamol-induced toxicity.^{172,173}

Young age has consistently been found to be a risk factor.^{151,173} Arterial ammonia concentration has been shown to correlate with death and cerebral herniation.^{158,159,173,176} Recent commentary suggests that arterial ammonia should be measured serially in all patients with ALF and that ICP monitoring be instituted if the concentration is greater than or equal to 150 $\mu\text{mol/L}$.¹⁷⁰

Serum sodium is often low in patients with ALF. In a consecutive group of patients with ALF from POD admitted to King's Hospital liver intensive care unit, 65% were hyponatremic on arrival (Will Bernal, personal communication). Hyponatremia is associated with a poor outcome in ALF,¹⁷⁷ and data have shown an inverse relationship between ICP and serum sodium in patients with ALF¹⁷⁸ (Box 75.3).

The severity of the inflammatory response and organ failure are positively associated with the risk of developing ICH. Systemic inflammation may exacerbate ICH in a brain primed by ALF.¹⁷³

Monitoring the Brain

There are a number of monitoring devices and methods that can be undertaken to screen for raised ICP or cerebral ischemia or both. Some of these devices are more invasive than others and the possible risks and benefits need to be understood.

Computed tomography is a standard investigation in any patient with suspected intracranial disease. Cerebral edema can be recognized in CT scans of patients with ALF and the severity correlates crudely to encephalopathy grade, but the correlation between imaging and severity of ICP measurement is poor.^{155,179} As little additional information is gained, very careful consideration should be undertaken before transporting this very sick group of patients to the CT scanner. Occasionally there are diagnostic difficulties or a

Box 75.3 Risk Factors for Brain Swelling in Acute Liver Failure

Are there risk factors for ICH?

- Less than 40 years of age
- Very low or high JV O_2 sat
- Significant organ dysfunction requiring support
- Severe hyponatremia <130 mmol/L
- Arterial ammonia >150 $\mu\text{mol/L}$
- Pupillary abnormalities or seizures
- High temperature, tachycardia, hypotension, signs of infection

Ammonia has long been implicated as important in hepatic encephalopathy and, as the evidence mounts, increasingly recognized as an important factor in the cause of cerebral edema in ALF.¹⁵⁷ Recent work has shown that whole blood ammonia predicts outcome and the chances of cerebral herniation.^{158,159} Electron microscopic analysis of postmortem brain biopsy together with gravimetric analysis of brain water content, in animal models, have shown that swelling occurs in the gray matter and that astrocytes are the main target.^{160,161} Ammonia may induce astrocyte swelling by a number of possible mechanisms. It is detoxified in astrocytes by combining with glutamate to produce glutamine. Astrocytes are the only cell type in the brain that contains glutamine synthetase, and this normal pathway maintains the ratio of glutamate to glutamine within astrocytes and neurons. The raised serum ammonia induces a buildup of glutamine within astrocytes, increasing the osmotic potential, absorption of water, and an increase in volume. Evidence of this effect can be inferred by the fact that inhibition of glutamine synthetase, which catalyzes the reaction, prevents brain swelling in experimental models.¹⁶² An osmotic effect may not be the only mechanism by which glutamine induces cellular swelling, however, but there is circumstantial evidence that it occurs to some extent. In subacute and chronic liver disease there is time for adaptation to the increase in astrocyte osmotic potential by the excretion of intracellular osmolytes such as myoinositol.¹⁶³ In ALF there is less time for adaptation because of the rapid increase in intracellular glutamine.

Other possible mechanisms include a breakdown in cellular energy metabolism induced by an increase in intracellular glutamine and ammonia. Impairment of α -ketoglutarate dehydrogenase and pyruvate dehydrogenase induced by oxidative stress and ammonia results in a breakdown in astrocyte energy production and an increase in glycolysis. This is supported by an increase in extracellular lactate and brain lactate flux in clinical studies.^{116,125} Mitochondrial dysfunction induced by ammonia may also play a role.¹⁵⁷

In addition to the cytotoxic edema seen early in ALF, changes in cerebral blood volume may play an important role in the development of ICH. Cerebral blood flow shows wide variation in patients with ALF, and the normal close relationship between cerebral metabolism and flow appears to be lost.¹⁶⁴ In animal models of liver failure there is a gradual increase in cerebral blood flow but this situation is less clear in human studies.^{156,165} Cerebral metabolism is generally reduced with high-grade encephalopathy in patients with ALF and there is evidence that relative or absolute cerebral hyperemia can contribute to ICH.^{131,166}

Patients with ALF often develop a systemic inflammatory response. Depending on the cause and severity of hepatic necrosis, damage-associated molecular pattern molecules and pathogen-associated molecular pattern molecules (DAMPs and PAMPs) are released from the liver. These, in turn, activate the innate and adaptive immune response culminating in the pathophysiologic picture associated with ALF. The severity of the inflammatory response has been shown to correlate with the degree of encephalopathy and the severity of ICH, and there is evidence that neuroinflammation in response to circulating cytokines exacerbates ICH.¹⁷¹

suspected complication of ICP bolt insertion and CT scanning might be considered.

Functional brain imaging, using single positron emission tomography (SPECT), has been used to investigate the distribution of cerebral blood flow in ALF and magnetic resonance imaging (MRI) scanning has been used to investigate the distribution of intracerebral water, but neither has found a place in clinical practice.^{126,180,181}

In patients with suspected ICH the direct monitoring of cerebral oxygenation and blood flow are appealing but current methods have technical and clinical limitations. Tissue Po_2 and interstitial metabolites, using intraparenchymal probes, have been investigated in traumatic brain injury and to a limited extent in ALF.^{116,182} They have the advantage in traumatic injury of providing localized information around the area of injury. The use of cerebral microdialysis (sampling of the cerebral interstitial fluid using a microcoaxial catheter with a semipermeable membrane) remains a research tool in ALF at the present time.

Methods used for the estimation of global cerebral oxygenation include the sampling of jugular venous (JV) blood for oxygen saturation, and products of metabolism such as lactate. A JV saturation of less than 55% suggests an ischemic brain. This can be due to a reduction in blood flow in excess of demand because of brain swelling or cerebral vasoconstriction due to hypocarbia, if the patient is being hyperventilated. An increase in demand due to seizure activity can also manifest as a reduction in JV saturation.¹⁸³ High jugular saturation (>80%) may represent a hyperemic brain, and steps can be taken to reduce cerebral blood volume if ICP is raised. Very high JV saturation is often seen as a terminal event and may represent a complete loss of oxygen extraction by the brain (Fig. 75.12).

Near infrared spectroscopy is a noninvasive technique used to assess the oxygen content of various organs. It can be used to determine cerebral oxygenation and changes

in cerebral perfusion in ALF and warrants further investigation.

Noninvasive measurement of cerebral blood flow using transcranial Doppler (TCD) has been investigated in ALF. In one study it was found to be predictive of changes in cerebral blood flow induced by hyperventilation.¹⁸⁴ More recent investigation has shown changes in TCD waveform as ICP increases, but it is not clear how reproducible these results are.¹⁸⁵

The recognition that ICP is raised in a significant proportion of patients with ALF and that this is implicated in significant rates of morbidity and mortality has led to the use of direct measurement of ICP with various forms of monitoring.^{151,186} These techniques, although fully supported internationally in traumatic brain injury, are controversial in the field of ALF and there remains a dichotomy of opinion in most countries, with some units using them and others not.^{153,154,187,188}

Controversy revolves around the lack of evidence of improved outcome with the monitoring of ICP and the risk of intracranial bleeding complicating insertion. The reported risk of bleeding, from survey data, is between 10% and 20% overall, the majority of which is not clinically significant. Mortality rate has been reported at between 1% and 3% (Alistair Lee, Edinburgh, UK, personal communication).^{186,188} The risk of bleeding following placement is higher than that seen following traumatic brain injury. There is uncontrolled evidence that activated factor VII can reduce this risk.¹⁸⁹

It has not been possible to prove that ICP monitoring improves survival in ALF, as a randomized controlled clinical trial has not been performed to evaluate it. However, it is generally accepted that medical intervention can reduce ICP and prevent cerebral ischemia and brain herniation in patients with ALF.¹⁷⁰ Published data suggest that having an ICP monitor increases the intervention rate compared to

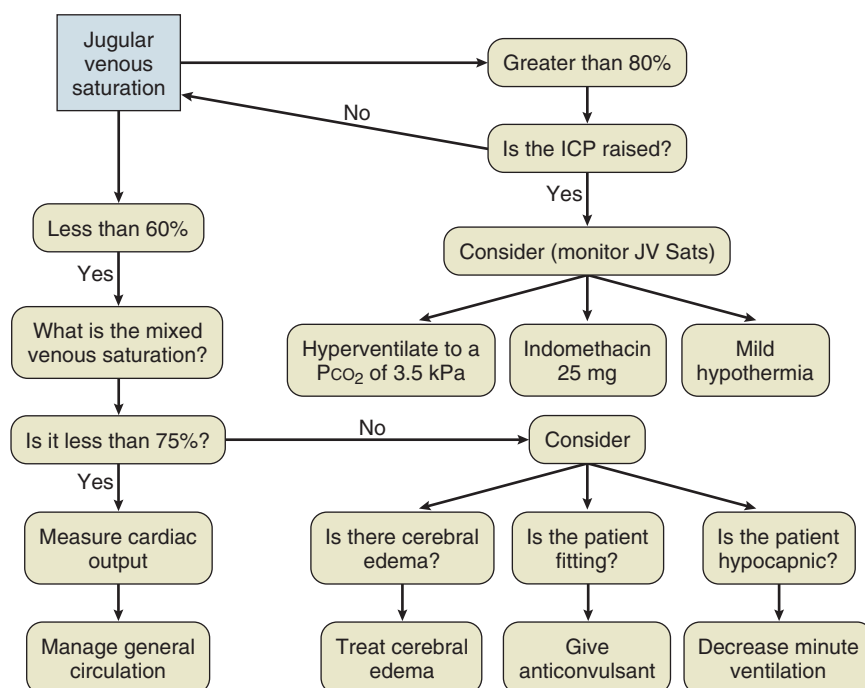

Figure 75.12 Monitoring cerebral oxygenation with jugular bulb sampling. ICP, intracranial pressure; JV, jugular venous; Sats, saturation.

patients without and increases the length of survival in the critical care unit, if not overall survival.¹⁹⁰ The majority of patients with ALF die of multiple organ failure due to sepsis. Intervention to reduce ICP may just prevent early cerebral death.

Although the risks of monitoring are documented, the risks of not monitoring are less clear. Without monitoring ICP there is a tendency toward therapeutic paralysis because of uncertainty and a tendency to manage all patients as if they had raised ICP. The reassurance of a normal ICP enables a reduction in sedation and paralysis. It enables tracheal suctioning and other nursing care without the uncertainty of worsening an unknown ICP. With ICP monitoring modest increases in ICP can be treated early before clinical signs suggest impending brain herniation. Monitoring ICP enables the calculation of cerebral perfusion pressure and, together with the monitoring of jugular oxygen saturation, allows a more complete picture of cerebral perfusion and oxygenation. The use of ICP monitoring has been advocated in the setting of liver transplantation for ALF and, of course, enables continued clinical research into the management of cerebral edema.

Prophylactic Measures

In patients at high risk of cerebral edema a number of prophylactic interventions have been shown to reduce the incidence of ICH.

Serum sodium is often low in patients with ALF. In a consecutive group of patients with ALF from POD admitted to King's Hospital liver intensive care unit, 65% were hyponatremic on arrival (Will Bernal, personal communication). Hyponatremia is associated with a poor outcome in ALF.¹⁷⁷ Based on retrospective data showing an inverse relationship between ICP and serum sodium in patients with ALF, moderate hyponatremia was investigated as a possible prophylactic intervention.^{119,178} Maintaining serum sodium between 145 and 155 mmol/L using hypertonic saline was found to reduce ICP from baseline and reduce the incidence of surges in ICP.¹¹⁹ Hypothermia improves outcome following out-of-hospital cardiac arrest and has been investigated in patients with traumatic brain injury. Early reports suggest hypothermia can reduce ICP and ammonia production in patients with ALF. However, prophylactic hypothermia has not been shown to reduce the incidence or improve outcome in this setting.¹⁹¹ Simple measures such as raising the head of the bed to a 30-degree angle and the avoidance of excessive stimulation are also prudent.

Cerebral Perfusion Pressure

In traumatic brain injury there is a consensus of opinion supporting the use of cerebral perfusion pressure (CPP) as a treatment goal.¹⁸⁷ In ALF the concept of CPP-directed therapy is less useful. To assume a correlation with cerebral blood flow there has to be a consistent cerebrovascular resistance, which is not the case in ALF.¹⁷⁰ This is due to the loss of cerebrovascular autoregulation, and attempts to increase cerebral perfusion are often unsuccessful as the use of a vasopressor results in an increase in ICP as brain blood volume increases.^{131,192} However, this is not to say that CPP should be ignored entirely but the safe lower limit of CPP has yet to be defined, as there are many reports of patients surviving with normal cerebral function despite a

low CCP.¹⁹³ The normal lower limit of cerebral autoregulation is reached at a mean arterial blood pressure of about 50 mm Hg, below which flow becomes pressure dependent. In patients with absent autoregulation, such as in ALF, CCP should probably be maintained above 40 mm Hg (the normal lower limit of autoregulation with an ICP of 10 mm Hg or less), but no data exist to back this statement up. Maintenance of CPP in ALF is best achieved by decreasing ICP and aiming for a mean arterial pressure with fluid and a vasopressor that does not increase ICP above 25 mm Hg. Attempting to improve cerebral oxygen balance is also attractive in this setting. This may be attempted with intravenous indomethacin (has been shown to improve CPP without compromising cerebral oxygenation), hypothermia, increased sedation, and hyperventilation.^{169,194-196} Monitoring cerebral oxygenation is very useful during such a maneuver.

General Management of Patients with Raised Intracranial Pressure

In patients at risk of or with suspected cerebral edema, prophylactic measures should be instituted. The decision to insert an ICP bolt or not will have to be made by the clinical team. If inserted, there is the potential to manage ICP.

ICP is normally less than 15 mm Hg in an adult. The definition of ICH is not precise and will vary among patients. Available data are derived from patients with traumatic brain injury (TBI) where observational studies suggest that intervention to reduce pressure should be instituted between 20 and 25 mm Hg, although pupillary abnormalities and brain herniation can occur at lower pressures.¹⁸⁷ There have not been any studies investigating treatment threshold in ALF and so similar thresholds to traumatic brain injury are used.

The management of ICH is usually escalated along standard algorithms (Figs. 75.13 and 75.14). Elevate the patient to an angle of 30 degrees and avoid tight straps around the neck to encourage venous drainage. ICP tends to increase during nursing intervention. If the ICP rises following nursing intervention and does not resolve after several minutes it implies poor intracranial compliance. Treatment is usually instituted for a sustained rise in ICP (more than 10 minutes over the treatment threshold) or clinical signs suggesting cerebral ischemia or impending herniation.

- Sedation should be increased. Propofol is probably the agent of choice.¹⁹⁴
- Osmotherapy is the mainstay of treatment following these simple measures.
 - Mannitol as a rapid infusion (0.5-1.0 g/kg) has been shown to reduce ICP reliably in ALF.¹⁹⁷ The dose can be repeated but care must be used in renal failure due to accumulation, and multiple administrations can result in a hyperosmolar syndrome. Plasma osmolality should be monitored if multiple doses are used. Current practice is to remove 500 mL of ultrafiltrate via CVVH following each bolus dose of mannitol.
 - Bolus doses of 20 mL hypertonic saline (30%) has a similar effect to mannitol in this setting in the author's experience. Hypertonic saline has a higher reflectance coefficient at the blood-brain barrier compared to

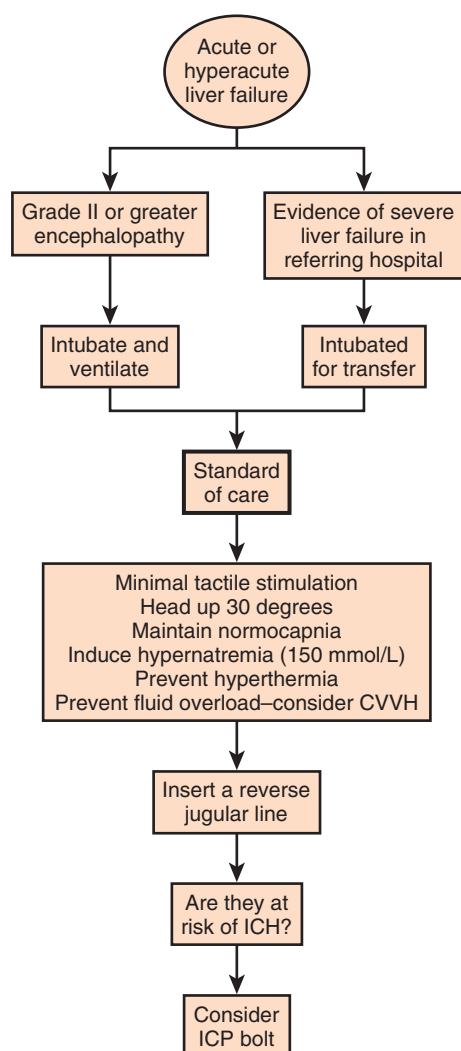

Figure 75.13 Initial management of patient with high-grade encephalopathy. CVVH, continuous venovenous hemofiltration; ICH, intracranial hypertension; ICP, intracranial pressure.

mannitol and there appears to be less tachyphylaxis to multiple administration.¹¹⁹

In patients with a raised ICP and cerebral hyperemia, suggested by a JV oxygen saturation of 80% or greater (luxury perfusion), short-term hyperventilation will induce cerebral vasoconstriction and reduce blood volume. This maneuver has been shown not to impair cerebral oxygenation but close monitoring of cerebral oxygenation should be employed if it is attempted.¹⁹⁵ Short-term hyperventilation has not been shown to improve outcome in ALF but does prolong survival in the ICU.¹⁹⁸ Hyperventilation may be lifesaving and may buy time for definitive treatment (transplantation). Indomethacin induces cerebral vasoconstriction and reduces ICP in patients with both traumatic brain injury and ALF without impairing cerebral oxygenation, although confirmatory studies are needed.¹⁶⁹

Seizures

Ammonia toxicity and cerebral edema are associated with seizure activity and it has been recognized that subclinical seizures occur more commonly than previously thought.¹⁸³

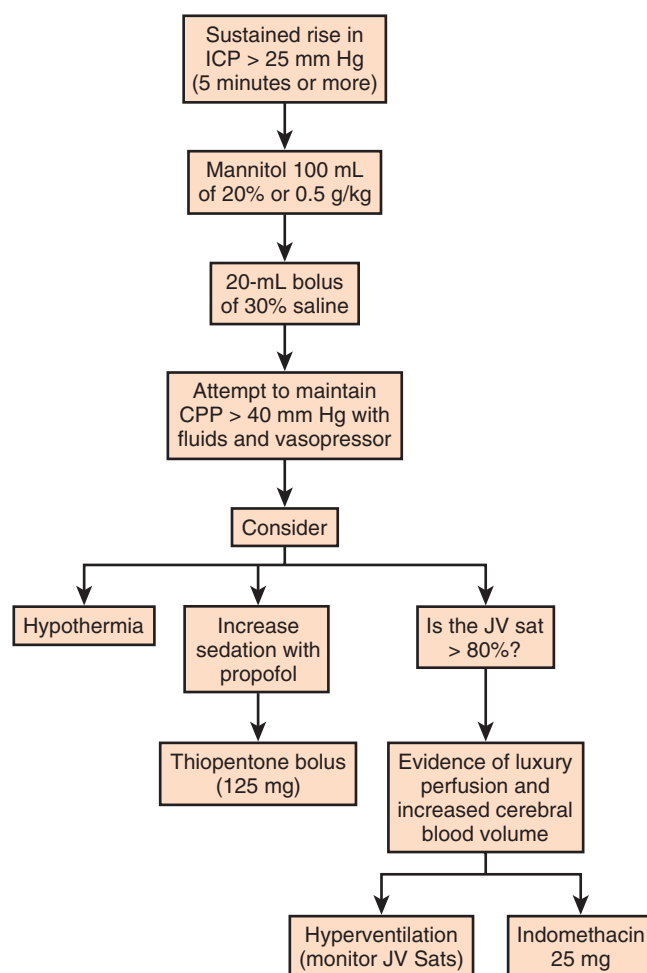

Figure 75.14 Management of a sustained rise in intracranial pressure. CPP, cerebral perfusion pressure; ICP, intracranial pressure; JV, jugular venous; Sats, saturation.

The use of mechanical ventilation facilitated by sedatives and muscular paralysis can mask clinical signs. Seizures adversely affect cerebral oxygen consumption and may contribute to cerebral edema and are a cause of low jugular oxygen saturation. It has been suggested that prophylactic phenytoin be used in all patients with ALF and high-grade encephalopathy. Others have questioned this approach because of the significant side effects and apparent lack of effect on outcome.¹⁹⁹ If confirmed, seizure activity should be managed along standard management guidelines.

INFECTION AND IMMUNOSUPPRESSION

Patients with ALF have multiple immune defects and are susceptible to infections.²⁰⁰ Infection is a common cause of progression and complication in ALF.²⁰¹ Antibiotic prophylaxis has been shown to reduce the incidence of infection and enable transplantation to proceed but has not been shown to improve survival. Selective decontamination of the digestive tract has not been shown to be superior to intravenous antibiotics alone.^{200,202} More recent work has shown how the microbiologic flora of a liver unit has changed over the past 20 years—for example, bacteremia appearing later in the ICU stay and being predominantly gram-negative in nature.²⁰³

It is current practice to prescribe broad-spectrum antibacterial and antifungal medication to patients with ALF depending on local sensitivities. There is a general trend to the timing of infection with gram-positive infections occurring earlier than gram-negative. Early gram-negative infections tend to be less resistant “endogenous” bacteria followed later by resistant hospital-acquired organisms.^{204,205}

NUTRITION

Within the general intensive care literature there is a consensus toward enteral nutrition (EN) as the route of choice.²⁰⁶ There are few additional data on which to base decisions in patients with ALF. There is, however, wide regional variation in the prescribing of parenteral nutrition (PN) compared to EN. The reason for this is unclear as EN is associated with a reduction in infectious complications.²⁰⁶ However, it is clear that some centers prefer PN.²⁰⁷ Nutritional requirements in ALF are not well understood.

ARTIFICIAL LIVER SUPPORT

At the present time liver transplantation is the only form of definitive therapy for severe hepatic failure. However, the scarcity of organs and potential for delay in transplantation, together with a proportion of patients who will make a full recovery if supported while the liver regenerates, suggest that there would be a role for some kind of liver support system.

The liver is a complex organ, and to be an ideal liver replacement, any system has to support a wide range of biosynthetic and metabolic functions. Any working system will also have to counter the systemic burden of the necrotic, dying liver.²¹⁶

Artificial liver support can be split into two main approaches. In the first there is an attempt to simulate or replace all or most of the functions of the liver. These systems include hepatocytes either from human or animal sources. Another view of liver failure suggests that toxins either excreted by the dying liver or not metabolized because of an acute reduction in function are responsible for the majority of the signs and symptoms. In this view extracorporeal blood purification with dialysis or adsorption techniques are employed and serum proteins not produced are replaced with plasma (Box 75.4).

BIOLOGIC SYSTEMS

Biologic systems consist of a bioreactor within which the cellular biomass is contained, and a mechanism of containing and separating the biomass from the circulation of the

patient. They require an extracorporeal system to deliver blood or plasma to the bioreactor and may also contain an adsorption or dialysis component. Data from liver resection suggest that approximately 250 mL of liver by volume is required to prevent death from liver failure. This typically represents 20% to 30% of liver mass.²¹⁷

NONBIOLOGIC SYSTEMS

Many of the molecules that accumulate within the blood during ALF are small or middle-sized.²¹⁶ These molecules can be targeted by a variety of extracorporeal purification techniques, including dialysis through various types of membranes and adsorption onto carriers such as charcoal, resins, or albumin.

LIVER TRANSPLANTATION

WHEN AND WHOM TO TRANSPLANT

Liver transplantation for ALF was used sporadically during the 1980s but gained pace in the late 1980s and now has a huge impact. It remains the only definitive form of therapy for some.

Timing is important, and in those with severe liver injury there is a window of opportunity beyond which transplantation often becomes futile because of deteriorating organ function.²²⁸ It was recognized early in the history of transplantation for ALF that the challenge was to develop robust prognostic indicators. These have to be sensitive, early enough to provide maximum advantage to the patient, and specific enough not to result in unnecessary transplants.

A “super-urgent” designation exists in the national transplant sharing scheme in the United Kingdom with a similar “category 1A” designation in the United States (see <http://www.unos.org/> for details). These categories recognize the role of early transplantation in ALF and the detrimental effect of delay in this setting.

In the United Kingdom, the super-urgent designation (Box 75.5) is closely linked to the prognostic score developed in King’s College Hospital in the late 1980s using retrospective multivariate analysis with prospective validation.²²⁹ The prognostic criteria have been subsequently validated in other centers and shown to be robust.²³⁰ Other criteria have been developed.²³¹

The criteria are not perfect. First, despite their good specificity (i.e., if the patient meets criteria the patient is likely to die), the sensitivity and negative predictive value are not as good, and there is a substantial proportion of patients who will die without ever reaching transplant criteria. In addition, awaiting positive criteria can lead to delay in listing and worsening of organ failure that often then preclude listing. This contributes to the fact that published rates of transplantation in those who reach criteria are only 50% following POD.²³² Clinical practice has changed since this designation was first defined. For example, it is rare to see a patient following POD with a pH below 7.3 or a creatinine above 300 mmol/L because of improved resuscitation and early renal support at the referring hospital. Because of these factors, ongoing efforts to establish markers that increase sensitivity and occur even earlier in the course of the syndrome, while maintaining good specificity and not reducing the positive predictive value to unacceptable levels leading to unnecessary transplants, continue.

Box 75.4 Functions of the Liver

- Excretion of bilirubin, cholesterol, hormones, and drugs
- Metabolism of fats, proteins, and carbohydrates
- Enzyme activation
- Storage of glycogen, vitamins, and minerals and regulation of glucose levels
- Synthesis of plasma proteins such as albumin, clotting factors, and bile production
- Blood detoxification and purification
- Immune regulation

Energy expenditure is raised during ALF. This is surprising considering the normal contribution of the liver, a large metabolically active organ, on the overall energy expenditure, illustrated by the effects of hepatectomy on energy expenditure during elective liver transplantation.²⁰⁸ There is organ-specific lactate production in both the liver and the lungs and evidence of a systemic inflammatory response in many patients.^{201,209,210} The cause of systemic inflammation in ALF is activation of inflammatory cells (leukocytes and endothelium) and the release of systemic cytokines. This may be initiated by infection.²⁰¹ Patients in the early stages of ALF are markedly catabolic with insulin resistance despite the frequent presence of a hypoglycemic state.²¹¹ The Harris-Benedict equation is inaccurate in ALF and indirect calorimetry should be used if energy requirements are sought.

Hypoglycemia is common as a result of the failure of both glycogenolysis and gluconeogenesis. Massive hepatic necrosis can result in a precipitous fall in serum glucose concentration. For this reason an infusion of 50% glucose should be used at least until feeding is established. Low-volume, high concentrations of glucose are preferred to reduce the infusion of large quantities of water and the resultant hyponatremia if lower concentrations are used.

Serum amino acids are consistently deranged during liver failure. There is a low or normal concentration of glutamine, branched chain amino acids, and tryptophan and an increase in others.²¹² High brain concentration of ammonia is thought to contribute to cerebral edema and encephalopathy in ALF. Manipulation of ingested amino acids has

been investigated in an attempt to reduce ammonia concentration. L-Ornithine and L-arginine (LOLA) infusion encourages alternate pathway metabolism and reduces hepatic encephalopathy in chronic liver disease.²¹³ LOLA has been investigated in animal models of ALF and resulted in normalization of plasma ammonia concentration, significant delay in the onset of encephalopathy, and a reduction in brain water concentration.²¹⁴ LOLA has been investigated in 2009 with a randomised controlled clinical trial in ALF. Despite theoretical promise, the investigators were unable to show any reduction in mortality rate or ammonia between the groups.²¹⁵

N-Acetylcysteine (NAC) is primarily used as a glutathione precursor and antidote in paracetamol poisoning but is used widely in patients with ALF induced by other causes and later on in its subsequent course. Results of a recent randomized controlled clinical trial have shown efficacy with NAC in patients with low-grade encephalopathy and nonacetaminophen-induced liver failure. The mechanism of action is unknown.⁷⁰

There is little evidence that protein restriction has any role in ALF, and protein requirements based on total calorie ingestion should be used.

Serum electrolytes are often deranged in the early stages of ALF. Hypophosphatemia is common in patients with ALF and is a good prognostic sign. High or normal phosphate may indicate a lack of hepatic regeneration and renal impairment.¹²⁰ Hypomagnesemia is also common and should be corrected.

Possible cell types to use as the biomass include animal or human primary hepatocytes or other forms of cell line with hepatocyte phenotype. Primary hepatocytes outperform other cell lines but are of limited availability and tend to have a time-dependent loss of hepatic phenotype. In addition, scaling up production with primary hepatocytes is difficult, as they do not readily undergo cell division under laboratory conditions. Instead, they have to be directly seeded into the bioreactor either immediately following harvest or following a period of storage and cryopreservation. Human cells are limited in availability but can be obtained from unused livers, following donation, and cut-down grafts. Theoretically, animal cells are readily available but uncertainty about possible cross-infection from animal pathogens to the patient with organisms such as PERV (porcine endogenous retrovirus) and incompatibility of secreted antigens render them far from ideal, and regulatory authorities are often reluctant to sanction their use.

Immortalized cell lines that proliferate in culture, while retaining some liver-specific functionality, can be used in an attempt to overcome the limitations of primary hepatocytes. Many lines have been created by retroviral transfection with regulatory genes that stimulate cell division. The insertion of “terminator” genes that give the cells a limited life or enable switching the immortalizing gene off have also been

developed to improve safety.²¹⁸ Other sources of immortal and readily cultured cells are tumor derived such as the ubiquitous Hep G2/C3A hepatoblastoma line. Finally, stem cell sources appear to offer the most hope in terms of a readily available and functional supply of differentiated hepatocytes.²¹⁹

Clinical trials in the use of bioartificial liver support have been relatively disappointing. The bioartificial liver (BAL) uses porcine hepatocytes and a charcoal column in series. The largest trial published so far in the field was powered for survival advantage in ALF and primary non-function following liver transplantation.²²⁰ The study was terminated early by the data and safety-monitoring board because the trial was likely to be futile based on the results at interim analysis.²²⁰ Post hoc analysis suggested some effect in the ALF group alone. The extracorporeal liver assist device (ELAD) system uses Hep G2/C3A hepatoblastoma line and has been investigated in a number of phase 1 and phase 2 studies designed to report safety and activity. In a randomized controlled study, not powered for mortality, showed a trend for improved survival in the treatment group.^{221,222} Since then, two further studies of the ELAD machine have been conducted in patients with AoCLD, both published as abstracts, both suggesting an improvement in outcome.^{223,224}

Nonbiologic systems are attractive because they are relatively inexpensive (compared to biologic systems) and logistically much easier to implement.

Early work with hemodialysis was unsuccessful and was largely abandoned with the conclusion that the toxemia of ALF was not due solely to small water-soluble molecules. The advent of synthetic membranes in the 1970s rekindled the interest in convective therapy for ALF. These allowed larger molecules to pass through compared to the cuprophane alternatives. Opolon reported clinical improvement with the use of high-permeability membrane hemodialysis and hemofiltration in patients with ALF.²²⁵ Hemofiltration, as a form of renal support, is used in most liver critical care units as part of general supportive care and there is some evidence that increased convective exchange, with high-volume (>35 mL/kg/hour) hemofiltration, is associated with improved hemodynamic stability and improved encephalopathy scores.^{145,225}

Charcoal hemoperfusion has been extensively investigated. Initial trials were encouraging, but later larger randomized controlled trials were unable to show an improvement in outcome.¹³⁷ Large volume plasma exchange showed some improvement in hemodynamics and other

parameters in initial studies.²²⁶ The therapy is logistically difficult to perform. However, in 2010 a large randomized controlled clinical trial of high-volume plasma exchange (10 L/day for 3 days) was presented and published in abstract form, showing improved survival, and it may become a standard form of therapy.²²⁷

In an attempt to improve the efficacy of dialysis techniques, adsorbents have been added to the dialysis fluid to widen the range of molecules removed. There are a number of approaches to doing this. One is dialysis of blood or plasma against albumin solution. This is done via a recycled circulation in the MARS machine or via single pass albumin dialysis. Another is the use of plasma separation, adsorption, and filtration and then recombining the “cleaned” plasma with the patient’s blood.²²³

Nonbiologic systems have been shown to improve blood pressure, increase vascular resistance, and improve short-term encephalopathy scores in patients with AoCLF. Three large studies have been reported, two in the management of AoCLF (the RELIEF study and the HELIOS study) and the FULMAR study in patients with ALF. Unfortunately, none of the studies has shown an improvement in outcome.²²³

Box 75.5 Prognostic Indicators for Liver Transplantation

Category 1: Paracetamol: pH <7.25 more than 24 hours after overdose and after fluid resuscitation

Category 2: Paracetamol: coexisting prothrombin time >100 seconds or INR >6.5, serum creatinine >300 $\mu\text{mol/L}$ or anuria, grade 3-4 encephalopathy

Category 3: Paracetamol: serum lactate >3.5 mmol/L on admission or >3.0 mmol/L more than 24 hours after overdose and after fluid resuscitation

Category 4: Paracetamol: two of three criteria from category 2 with clinical evidence of deterioration (e.g., increased ICP, FiO_2 >50%, increasing inotrope requirements) in the absence of clinical sepsis

Category 5: Etiology: hepatitis A, hepatitis B, idiosyncratic drug reaction, seronegative hepatitis; prothrombin time >100 seconds or INR >6.5 and any grade of encephalopathy

Category 6: Etiology: hepatitis A, hepatitis B, idiosyncratic drug reaction, seronegative hepatitis; any grade of encephalopathy and any three from the following: unfavorable etiology (idiosyncratic drug reaction, seronegative hepatitis), age >40 years, jaundice to encephalopathy time >7 days, serum bilirubin >300 $\mu\text{mol/L}$, prothrombin time >50 seconds or INR >3.5

Category 7: Etiology: acute presentation of Wilson's disease, acute presentation of Budd-Chiari syndrome; combination of coagulopathy and any degree of encephalopathy

Category 8: Hepatic artery thrombosis within 14 days of liver transplantation

Category 9: Early graft dysfunction with at least two of the following: AST >10,000, INR >3.0, serum lactate >3 mmol/L, absence of bile production

AST, aspartate transaminase; ICP, intracranial pressure; INR, international normalized ratio.

Serum phosphate levels are higher in nonsurvivors following both POD and in other causes of ALF.^{120,233} However, there appears to be an unacceptable overlap and others have suggested that the use of serum phosphate does not provide any additional benefit to existing markers.^{121,234,235} Other factors investigated include α -fetoprotein levels and nuclear magnetic resonance (NMR) analysis of peripheral blood.^{120,236} Acute physiologic scoring as a basis for prediction has also been utilized.²³⁷

The liver plays a central role in lactate metabolism. In fact, in patients with severe liver necrosis the liver changes from being a consumer of lactate to being a net producer.²⁰⁹ Arterial blood lactate levels have been shown to improve the sensitivity and maintain the specificity if added to the original King's College Hospital criteria and are achieved earlier in the course of the syndrome.¹⁴⁹ However, the additional advantage of lactate over the original criteria has been questioned by some.²³⁸

On the practical issue of actually managing patients with fulminant hepatic failure some room for clinical interpretation has been included in the super-urgent listing rules. For example, there is a group of patients who do not achieve King's College Hospital criteria but subsequently die, usually of cerebral edema or multiple organ failure secondary to

PATIENT SURVIVAL ACCORDING TO THE INDICATION
01/1988–12/2010

Figure 75.15 Patient survival according to the first indication for liver transplant. (From European Liver and Intestine Transplant Association, accessed at <http://www.eltr.org>.)

sepsis.^{172,175} These patients often have worse acute physiologic scores compared to survivors.^{232,237} As a result the U.K. super-urgent criteria allow an assessment of deteriorating acute physiology based on cardiovascular, respiratory, or cerebral disease. Similarly, the UNOS 1A criteria allow for patients “not expected to survive a further 7 days.”

OUTCOME FROM TRANSPLANTATION

In Europe the 1-year survival rate following transplantation for ALF is worse than that seen in chronic liver disease. The excess mortality rate is seen in the first month or so after transplantation. This represents the severity of organ dysfunction seen prior to transplantation in ALF. Following this initial period, the curve flattens and the survival rate is actually better than that of patients with chronic liver disease (Fig. 75.15). This probably represents a younger age group and less disease recurrence. There is a huge degree of heterogeneity in ALF, and those transplanted with seronegative hepatitis display a better survival profile than patients transplanted for other causes, although they exhibit a similar early mortality rate while in the ICU.⁸⁹

A tremendous amount of research effort has been put into the search for prognostic criteria on which to base the decision to transplant patients with ALF; however, much less information is available about the prediction of fatality following transplantation. This is important, as decisions to withdraw from the waiting list based on severity are difficult.

There appear to be both recipient and donor factors that help predict the outcome from transplantation in ALF.^{89,232,239} In theory, the severity of illness and organ dysfunction prior to transplantation should predict outcome. However,

because unstable patients tend to be either not listed or withdrawn from the waiting list, there is inherent bias in retrospective analysis. Age of the recipient is a significant factor, certainly for seronegative ALF, but also in POD, in which age is often used to exclude listing.²³² In non-paracetamol ALF, serum creatinine at the time of transplantation is a predictor of 2-month survival. Following POD, time from ingestion to transplantation has been shown to be a good predictor of 2-month survival; all patients transplanted later than 6 days from ingestion died. APACHE III score at transplantation and the severity of metabolic acidosis are also predictive.²³⁹

Donor factors found to be important are the use of reduced size grafts in paracetamol-induced ALF and evidence of early graft dysfunction as defined by a high AST or INR in the early postoperative period. In addition a high donor body mass index (BMI) is a risk factor for death in seronegative hepatitis.^{89,232}

In 2012 a review of the European liver transplant database for patients transplanted following ALF was done in which 4903 patients were evaluated. The 1-, 5-, and 10-year patient and graft survival rates were 74%, 68%, and 63%, respectively. Death and graft loss were independently associated with male recipients, recipients older than 50 years, incompatible ABO matching, donors older than 60 years, and reduced size graft. Recipients over 50 receiving a graft >60 years old had a 57% 1-year mortality rate or graft loss.²⁴⁰

The conclusions from this review suggest that older recipients with severe preoperative organ dysfunction are less able to tolerate poor early graft function, often seen with marginal grafts. Therefore, in order to achieve the best graft and patient survival there should be matching of the organ to the recipient, but this is difficult because of time constraints.

AUXILIARY TRANSPLANTATION

Auxiliary partial liver transplantation has many theoretical advantages compared to standard orthotopic transplantation in ALF. It can be performed orthotopically (i.e., in the same place as the original liver) or heterotopically (e.g., in the left iliac fossa). These days it is always performed as a partial orthotopic transplant with a native left lobe in situ in adults and a right lobe in children using an adult left lobe graft, depending on size.

It provides the potential to support the patient during the acute phase of liver failure, enabling regeneration of the native liver. This is attractive because in a number of patients immunosuppressive drugs can be withdrawn, allowing the graft to atrophy or be removed, and eliminating the risks associated with lifelong immunosuppression. Data on this procedure have been accumulating since the mid-1990s. Initial reports suggested that the procedure was associated with a high incidence of technical problems, primary dysfunction, and retransplantation. Later reports, however, suggest that many of these issues are resolving with greater experience in patient and graft selection. The best outcome has been seen in patients aged younger than 40 years with either acute viral hepatitis or paracetamol hepatotoxicity in which 1-year graft and patient survival are similar to those for standard transplantation for ALF. Withdrawal of immunosuppression can be achieved in 30% to 70% of patients transplanted.²⁴¹⁻²⁴³

LIVING RELATED LOBE DONATION

In many countries the only chance of transplantation for ALF is in a living related donation of a liver lobe. This is most often performed in children when an adult left lobe can be used. In adults, a right lobe is usually required, increasing the risk to the donor. With the worldwide shortage of donor organs, living related transplantation for ALF is widely accepted in many countries but not all. There are significant issues related to living related transplantation in ALF including a donor mortality rate of 1% and major morbidity rate of 40% to 60%. There are also ethical implications of adequately preparing the donor, medically and psychologically, in a time of acute crisis.²⁴⁴

KEY POINTS

- Liver failure can occur with a background of cirrhosis, when it is often termed *acute on chronic liver failure* (AoCLF), or it can occur de novo in a previously healthy individual due to a toxic, immunologic, hypoxic, or infective cause, when it is termed *acute liver failure* (ALF) or fulminant liver failure.
- Liver failure, defined by the onset of hepatic encephalopathy and progressive failure in hepatic metabolic activity, progresses to multiple organ failure and ultimately death in a large proportion of patients, and supportive care is the mainstay of therapy.
- AoCLF is seen much more commonly than ALF. It is most often seen in the setting of advanced, decompensated cirrhosis with portal hypertension. It is usually precipitated by some intercurrent event such as sepsis or an upper gastrointestinal bleed. Therapy is aimed at the treatment of sepsis and aggressive management of the circulation.
- Worldwide, particularly in the developing world, approximately 95% to 100% of patients presenting with ALF will have viral hepatitis.
- Acetaminophen poisoning is the most common cause of ALF in northern Europe and the United States. It can be treated successfully in the majority of patients with NAC, if given within the first 12 hours following nonstaggered ingestion.
- The presentation and clinical course of ALF depends on its cause and the rate of progression of the syndrome.
- Liver failure following viral hepatitis is rare and tends to run an acute or hyperacute course, with the onset of encephalopathy occurring within days or weeks of the first symptoms.
- The West Haven criteria, designed to assess coma grade in patients with cirrhosis, are often applied to patients with ALF and are useful because of their familiarity.
- Intracranial hypertension secondary to cerebral edema often complicates severe hyperacute liver failure and remains a leading cause of death.
- Management of ALF is complex, and liver transplantation is the only effective therapy in severe cases.

CONCLUSION

Gastrointestinal (GI) bleeding encompasses a wide range of diagnoses with multiple types of lesions and bleeding that can occur virtually anywhere in the GI tract. Acute GI bleeding is often an emergency that can be alarming to both the patient and physician. Management and the outcome of GI bleeding depend on both the severity of the bleeding and any comorbid conditions present at the time of the bleeding. Acute GI bleeding often requires close monitoring and management in an intensive care unit (ICU). Management of such bleeding relies on a team approach that involves the expertise of an intensivist, gastroenterologist (endoscopist), radiologist, and surgeon.

More than 300,000 annual hospitalizations in the United States are attributed to GI bleeding.¹ Upper GI bleeding accounts for most of these hospitalizations, with an incidence rate of 100 cases per 100,000,¹ whereas the incidence of lower GI bleeding is estimated at 20 to 27 cases per 100,000.^{2,3} Mortality rates vary depending on the source of the bleeding. Most nonvariceal upper GI bleeding studies document mortality rates approximating 10%.^{4,5} These rates have not changed over the past 2 decades despite the evolution of acid suppression therapy, which is probably explained by an aging population with increased comorbid diseases. Mortality rates for lower GI bleeding are usually in the range of 5%.^{6,7}

CLINICAL PRESENTATION

INITIAL EVALUATION AND RESUSCITATION

The clinical findings in a patient with GI bleeding are crucial in determining the site, cause, and rate of bleeding.

The first step in clinical evaluation is to assess the severity of the bleeding. This is done primarily by measuring hemodynamic parameters in an attempt to quantify the amount of blood volume lost (Table 76.1).⁸ Because bleeding can represent a dynamic ongoing situation, continuous monitoring of hemodynamics is necessary to guide resuscitation efforts and provide key prognostic information. In patients with GI bleeding, two large-bore intravenous catheters should be placed immediately on arrival to restore euolemia.

The hematocrit at initial evaluation may not reflect the severity of the bleeding because very recent loss of both plasma and red blood cells leads to a percentage of red blood cells in the remaining blood (which defines the hematocrit) that is close to the same value. The hematocrit drops when hemodilution occurs as extravascular fluid enters the vascular space to restore volume, a process that may take up to 72 hours (Fig. 76.1).⁹

The rapidity of blood and colloid infusion depends in part on the patient's cardiovascular condition. Placement of a central venous pressure catheter can help one base decisions on more objective findings. Several recent studies found that transfusion was associated with higher risk for nosocomial infection, multiorgan dysfunction, acute respiratory distress syndrome, and death.¹⁰ Current transfusion trends are to administer blood to patients with hemoglobin less than 7 mg/dL and to avoid transfusion when it's above 10 mg/dL. However, the threshold for blood transfusion should take into consideration the patient's underlying condition, hemodynamic status, and markers of tissue hypoxemia.¹¹ In patients with conditions associated with defects in platelet or coagulation factors, these substances should be replaced. Patients requiring massive transfusion of packed

Table 76.1 Hemodynamics, Vital Signs, and Blood Loss

Hemodynamics and Vital Signs	% Blood Loss (Fraction of Intravascular Volume)	Bleeding Type
Shock (resting hypotension)	20-25	Massive
Postural (orthostatic tachycardia or hypotension)	10-20	Moderate
Normal	<10	Minor

From Rockey DC: Gastrointestinal bleeding. *Gastroenterol Clin North Am* 2005;34:581-588.

Figure 76.1 Plasma volumes (solid bars), red blood cell volumes (pale bars), and hematocrit values (%) before bleeding and after blood loss of 2 L. A baseline hematocrit level of 45% is assumed. (From Rockey DC: Gastrointestinal bleeding. In Feldman M, Friedman LS, Sleisenger MH [eds]: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease*, 7th ed. Philadelphia, WB Saunders, 2002, pp 221-248.)

red blood cells require fresh frozen plasma and platelets. Hypocalcemia can develop in these patients because of the large amount of citrate received with massive transfusion, and thus calcium replacement should be considered, especially in individuals with end-stage liver disease and heart failure, in whom citrate metabolism may be impaired.¹² The initial evaluation of patients with nonvariceal upper GI bleeding should include risk stratification of patients into low- and high-risk categories for rebleeding and death based on clinical, laboratory, and when available, endoscopic criteria.¹⁰ This allows appropriate intervention and minimizes morbidity and mortality risks. The most extensively validated scores for risk stratification are the Blatchford and Rockall scores^{13,14} (Tables 76.2 and 76.3). Similarly, risk stratification in lower GI bleeding helps in guiding the management of these patients. Hemodynamic instability, ongoing hematochezia, and comorbid illnesses have been consistently associated with poor outcome in lower GI bleeding.¹⁵

Table 76.2 Blatchford Score for Gastrointestinal Bleeding*

Admission Parameter	Score Value
Urea (mg/dL)	
≥6.5 to <8.0	2
≥8 to <10	3
≥10 to <25	4
≥25	6
Hemoglobin (g/dL)	
Men	
≥12 to <13	1
≥10 to <12	3
<10	6
Women	
≥10 to <12	1
<10	6
Systolic blood pressure (mm Hg)	
100 to 109	1
90 to 99	3
<90	3
Other parameters	
Pulse >100	1
Melena at presentation	1
Syncope	2
Hepatic disease	2
Cardiac failure	2

*The score is calculated by adding the points from each variable. A score of zero is associated with a low risk of the need for endoscopic intervention

From Blatchford O, Murray WR, Blatchford M: A risk score to predict need for treatment for upper-gastrointestinal haemorrhage. *Lancet* 2000;356:1318-1321.

Box 76.1 Historical Features in the Assessment of Gastrointestinal Bleeding

Age
Previous bleeding
Previous gastrointestinal disease
Previous surgery
Underlying medical disorder (especially liver disease)
Nonsteroidal anti-inflammatory drugs
Abdominal pain
Change in bowel habits
Weight loss or anorexia
History of oropharyngeal disease

From Rockey DC: Gastrointestinal bleeding. *Gastroenterol Clin North Am* 2005;34:581-588.

HISTORY AND CLINICAL FINDINGS

After hemodynamic stabilization is achieved, a careful history and clinical examination are imperative to make a preliminary assessment of the location and cause of the bleeding. Important historical features in the evaluation of GI bleeding are shown in Box 76.1.⁸

Hematemesis typically points to an upper source of bleeding, proximal to the ligament of Treitz. In rare cases,

Table 76.3 Rockall Scoring System for Risk of Rebleeding and Death in Acute Gastrointestinal Bleeding*

Variable	Points			
	0	1	2	3
Age (years)	<60	60 to 79	>80	
Shock	No shock (systolic BP >100 mm Hg, pulse <100)	Tachycardia (systolic BP >100 mm Hg, pulse >100)	Hypotension (systolic BP <100 mm Hg, pulse >100)	
Comorbidity	Nil major		Cardiac failure, ischemic heart disease, any major comorbid condition	Renal failure, liver failure, disseminated malignancy
Diagnosis	Mallory-Weiss tear, no lesion, and no SRH	All other diagnoses	Malignancy of upper GI tract	
Major SRH	None or dark spot		Blood in upper GI tract, adherent clot, visible or spurting vessel	

BP, blood pressure; GI, gastrointestinal; SRH, stigma(ta) of recent hemorrhage.

*The score is calculated by adding the points from each variable. A score of 2 or less is associated with a low risk of further bleeding or death.

From Rockall TA, Logan RF, Delvin HB, et al: Risk assessment after acute upper gastrointestinal haemorrhage. *Gut* 1996;38:316-321.

hematemesis can be a sign of swallowed blood from oral, pharyngeal, or nasal bleeding. Melena is defined as black tarry stool with a glistening sheen and results from degradation of blood in the GI tract. At least 50 mL of blood in the upper GI tract is required to cause melena, although volumes up to 100 mL may be clinically silent.¹⁶ Melena usually indicates upper GI bleeding, but its source may be the small bowel and sometimes even the proximal part of the colon when the volume of blood is too small to cause hematochezia. Coffee-ground emesis is typically a sign of recent, but currently inactive upper GI bleeding, and its appearance is caused by the acid's effect on blood in the lumen. Hematochezia is generally associated with colonic bleeding but can also be caused by more proximal bleeding. Proximal bleeding in association with hematochezia is usually more hemodynamically significant.

Other symptoms at initial evaluation can help in narrowing the differential diagnosis. Abdominal pain before or at the time of the bleeding episode can be a sign of underlying peptic ulcer disease (PUD), mesenteric or colonic ischemia, perforation, or even intestinal infarction. Multiple episodes of vomiting and retching preceding the bleeding episode should alert one to the presence of a Mallory-Weiss tear.

A previous history of bleeding from PUD, esophageal or gastric varices, diverticulosis, or vascular ectasia puts these diagnoses high on the differential diagnosis list. A history of abdominal vascular surgery adds aortoenteric fistula to this list. In patients with known liver disease, the possibility of bleeding from conditions associated with portal hypertension, such as esophageal or gastric varices and portal gastropathy, should be raised. One should also look for risk factors for chronic liver disease, such as a history of chronic alcohol abuse and chronic hepatitis.

GI bleeding in elderly patients is usually caused by conditions less commonly encountered in younger patients (i.e., diverticulosis, vascular ectasia, ischemic colitis), whereas in younger patients, bleeding from sources such as varices, ulcer disease, and esophagitis is more common.

Ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) increases the risk of bleeding from PUD. In patients taking anticoagulant medications, bleeding most often results from underlying GI disease such as ulcer disease or vascular ectasia, even in the setting of a supratherapeutic international normalized ratio, and should not be attributed to the anticoagulation itself.

Other medical conditions present at the time of the bleeding can have a large impact on the resuscitation efforts and subsequent management. Bleeding patients with a history of coronary artery disease are at increased risk for myocardial infarction, and restoration of volume and oxygenation should be an immediate goal. Patients with pulmonary disease may need airway intubation before sedation when endoscopy is being contemplated.

Physical examination should look for evidence of chronic liver disease such as spider angiomas, gynecomastia, splenomegaly, and ascites. The presence of these signs suggests the possibility of portal hypertension. Telangiectases of the skin or mucous membranes and lips raise the possibility of hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease). Acanthosis nigricans can be a sign of GI malignancy (especially gastric cancer). The presence of purpura suggests vascular diseases such as Schönlein-Henoch purpura or polyarteritis nodosa. Tenderness with or without peritoneal signs on abdominal examination may indicate PUD, ischemia, or perforation. The abdominal examination should include percussion and palpation to look for organomegaly and masses. Bedside examination of the character of the stool is a necessary measure that provides critical information about the source and severity of the bleeding episode. Bright red blood per rectum, maroon-colored stools, and melena suggest active bleeding, whereas brown stools indicate less aggressive bleeding.

The use of a nasogastric tube in patients presenting with GI bleeding is a common practice but at the same time controversial. The presumed benefits of nasogastric lavage include confirmation of an upper GI source of bleeding,

better visualization during endoscopy, and prediction of high-risk lesions such as an oozing or spurting lesion and nonbleeding visible vessel. A bloody aspirate suggests, with some degree of certainty, an upper source of bleeding because false-positive results are rare and generally related to nasogastric trauma.¹⁷ In one study looking at patients presenting with suspected upper GI bleeding, 45% of cases with a bloody aspirate were associated with a high-risk lesion on endoscopy versus 15% when the aspirate was clear or bilious.¹⁸ Identifying patients with high-risk lesions is important because those patients have the worst outcome and early endoscopic therapy may have the most benefit. However, the positive and negative predictive values of a bloody aspirate for high-risk lesions are only 45% and 85%, respectively, which makes basing the decision of an early endoscopy on the information obtained by the nasogastric lavage controversial. In a recent retrospective study looking at the impact of performance of nasogastric lavage, this practice was associated with earlier time to endoscopy but had no effect on mortality rate, length of hospital stay, surgery, or transfusion requirements.¹⁹ In our opinion, if an upper endoscopy is planned in the next 12 to 24 hours after presentation of a patient with suspected upper GI bleeding, nasogastric lavage should be avoided owing to lack of proven benefit and major discomfort and pain inflicted to the patient. In the setting of hematochezia with hemodynamic instability, extremely brisk upper GI bleeding should be suspected, and a positive nasogastric aspirate can confirm this suspicion.

DIAGNOSTIC TESTS

The initial laboratory evaluation in patients with GI bleeding should include a complete blood count, liver enzymes, prothrombin time, blood urea nitrogen (BUN), and creatinine. As mentioned earlier, the first hematocrit level may be falsely reassuring, so management decisions should rely on other parameters such as hemodynamics and the nature of the bleeding. A high white blood cell count should alert one to the presence of ischemia or infarction. Thrombocytopenia can be a sign of portal hypertension, and a critically low platelet count, as well as a high prothrombin time, should be addressed immediately by transfusion of platelets and fresh frozen plasma. An elevation in the BUN level out of proportion to creatinine is compatible with upper GI bleeding but may also be seen with intravascular volume depletion from any source of bleeding. In one study, this ratio was significantly higher in patients with upper GI bleeding than in those with lower GI bleeding (22.5 ± 11.5 vs. 15.9 ± 8.2 ; $p = 0.001$); however, the degree of overlap shows the poor discriminatory value of this ratio.²⁰ In another study, a ratio greater than 36 had a specificity of 27% and a sensitivity of 90% for upper GI bleeding.²¹

After initial resuscitation and stabilization, a diagnostic plan should be initiated. Several diagnostic tools are available, including endoscopy, radionuclide imaging, and angiography. These tests are aimed at detecting the location, source, and activity of bleeding. Other tests may be necessary in specific clinical situations, such as computed tomography (CT) scanning when abdominal pain is a prominent complaint to rule out ischemia, infarction, and perforation.

Endoscopy and to some extent angiography have the advantage of allowing both diagnosis and therapy.

THERAPEUTIC OPTIONS

In addition to controlling the current episode of bleeding, treatment is also aimed at preventing recurrent bleeding. The available forms of therapy are pharmacologic, endoscopic, angiographic, and surgical. They are often complementary and require a multidisciplinary team approach. Use of these different modalities varies with the specific cause and source of bleeding.

Advances in potent acid suppression with the advent of proton pump inhibitors (PPIs) and the progress made in endoscopic technology have revolutionized the management of GI bleeding. Effective acid suppression has an established role in decreasing bleeding recurrence. Different endoscopic treatment modalities can be used alone or in combination during endoscopy and have been shown to decrease bleeding recurrence. Such modalities include injection, cautery, and mechanical therapy.

Detailed approaches to the diagnostic and therapeutic options will be highlighted in specific sections of this chapter.

UPPER GASTROINTESTINAL BLEEDING

DIFFERENTIAL DIAGNOSIS

NONVARICEAL BLEEDING

Nonvariceal upper GI bleeding remains a significant cause of death and morbidity despite recent advances in pharmacologic and endoscopic therapy. The cause of nonvariceal bleeding encompasses a large array of diagnoses involving multiple organs above the ligament of Treitz and at times outside the GI tract. The causes and frequency of nonvariceal bleeding are listed in Table 76.4.²²

Peptic Ulcer Disease

PUD traditionally refers to gastric and duodenal ulcers, gastritis, and duodenitis. A number of population-based and

Table 76.4 Causes of Nonvariceal Upper Gastrointestinal Bleeding

Diagnosis	Incidence (%)
Peptic ulcer	30-50
Mallory-Weiss tear	15-20
Erosive gastritis or duodenitis	10-15
Esophagitis	5-10
Malignancy	1-2
Angiodysplasia or vascular malformations	5
Other	5

Figure 76.2 **A**, Mallory-Weiss tear in the cardia of the stomach. Active bleeding is seen. **B**, The same tear seen in **A** after injection with epinephrine and coagulation. The bleeding is controlled. (From Schmulewitz N, O'Connor JB: Esophageal disease caused by medication, radiation and internal trauma. In DiMarino AJ, Benjamin S [eds]: *Gastrointestinal Disease: An Endoscopic Approach*, 2nd ed. Thorofare, NJ, Slack, 2002, pp 245-262.)

prospective studies rank PUD as the most common source of acute upper GI bleeding, with PUD representing up to 50% of all such cases.²³ However, recent analysis from the Clinical Outcomes Research Initiative (CORI) database reported that the most common endoscopic finding in persons with acute upper GI bleeding was “mucosal abnormality” (40%), and gastric or duodenal ulcers were found in 20.6%.²⁴ Eradication of *Helicobacter pylori* and extensive use of PPIs are probably responsible for this observed decline in the frequency of PUD.

The most important factors predisposing to ulcer disease include acid, *H. pylori* infection, and NSAIDs; however, the role of some of these risk factors in inducing ulcer bleeding remains unclear. Indirect evidence regarding the role of acid in ulcer bleeding comes from data showing that acid suppression by PPIs in patients with active or recent bleeding reduces the risk for rebleeding.²⁵ Evidence of the association between NSAIDs and ulcer bleeding is strong and comes from both placebo-controlled and case-control studies.^{26,27}

The pathogenesis of bleeding from an ulcer involves aneurysmal dilation with an intense arteritis associated with a marked inflammatory response.²⁸ When eroding into large vessels, ulcers can cause catastrophic bleeding. This most commonly occurs in the posterior portion of the duodenal bulb, where ulcers can erode directly into the pancreaticoduodenal artery.

Other Sources of Nonvariceal Upper Gastrointestinal Bleeding

Mallory-Weiss tears (MWTs) are mucosal and occasionally submucosal lacerations caused by sudden increases in pressure within the cardia and lower esophagus produced by retching. MWTs are responsible for 5% to 15% of upper GI bleeding.²³ The majority of upper GI bleeding caused by MWTs stops spontaneously and does not require any blood

transfusion or endoscopic treatment. However, some cases are severe enough to require endoscopic hemostasis and occasionally angiography with embolization or even surgery. A history of retching on arrival at the emergency department is not always present.²⁹ Endoscopically, tears are usually 1.5 to 2 cm in length and occur at the gastroesophageal junction or, most commonly, in the proximal part of the stomach (Fig. 76.2).

Angiodysplasia, also referred to as arteriovenous malformation or vascular ectasia, is another source of upper GI bleeding and accounts for approximately 5% to 10% of cases.²³ It occurs in inherited syndromes such as hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) and blue rubber bleb nevus syndrome, but most cases are acquired.³⁰ The association of angiodysplasia with medical conditions such as renal failure, aortic stenosis, connective tissue disease (scleroderma), and von Willebrand disease has been recognized, but the evidence for these associations is limited.^{23,31}

Dieulafoy's lesion is an underrecognized cause of upper GI bleeding and is described as a visible vessel protruding from a small mucosal defect without any underlying ulcer.²³ It has also been called “caliber-persistent artery” in submucosal tissue. Bleeding from Dieulafoy's lesion represents less than 5% of cases of upper GI bleeding.^{32,33} The lesion is generally located on the lesser curvature within 6 cm of the gastroesophageal junction and can be difficult to detect because of its small size and normal surrounding mucosa (Fig. 76.3).³¹

Benign and malignant neoplasms are responsible for less than 5% of upper GI bleeding.³⁴ Bleeding can be the initial symptom of tumors originating from the esophagus, stomach, or small intestine. These neoplasms can be primary malignancies, such as adenocarcinoma of the esophagus, stomach, or duodenum; squamous cell carcinoma of the esophagus; and gastric or duodenal lymphomas.

Figure 76.3 A and B, Endoscopic appearance of Dieulafoy's lesion in the proximal part of the stomach. (From Bashir RM, Al-Kawas FH: Vascular lesions of the stomach. In DiMarino AJ, Benjamin S [eds]: *Gastrointestinal Disease: An Endoscopic Approach*, 2nd ed. Thorofare, NJ, Slack, 2002, pp 535-550.)

Gastrointestinal stromal cell tumors (GISTs), carcinoid tumors, and lipomas are examples of benign tumors that can cause upper GI bleeding.²³

Upper GI bleeding from an aortoenteric fistula is very rare but should be considered in the appropriate clinical setting (such as a patient with a history of aortic aneurysm repair). Fistulas are generally located in the third portion of the duodenum. Patients will frequently have a small hemorrhage first, known as a “herald bleed,” that occurs before a major hemorrhage.³⁵

Another rare cause of upper GI bleeding is hemobilia. It can occur after liver biopsy or hepatobiliary tree instrumentation (such as with endoscopic retrograde cholangiopancreatography [ERCP]) or from biliary tumors.

Hemosuccus pancreaticus is an uncommon cause of upper GI bleeding that occurs secondary to pseudoaneurysm formation and rupture into the pancreatic duct as a complication of a pancreatic pseudocyst in patients with chronic pancreatitis.³⁶

BLEEDING SECONDARY TO PORTAL HYPERTENSION

Portal hypertension is defined by a hepatic venous pressure gradient (HVPG) greater than 5 mm Hg. HVPG represents the difference between portal vein pressure and free hepatic vein pressure. Portal hypertension is most commonly related to cirrhosis but can be secondary to a variety of other conditions. It has been classified as prehepatic, hepatic, and post-hepatic, depending on the location of the obstruction to flow. Examples of noncirrhotic portal hypertension include portal vein thrombosis, Budd-Chiari syndrome, and constrictive pericarditis. In the presence of portal hypertension, the development of portosystemic collateral venous drainage results in the formation of varices. Varices develop most commonly in the distal portion of the esophagus and the stomach. Ectopic varices can be seen in the duodenum, jejunum, or colon; at the level of stomas (ileostomy and colostomy); and in the anorectal region.

Most portal hypertensive bleeding results from ruptured esophageal varices, but clinically significant bleeding can also be secondary to gastric varices, portal gastropathy, and ectopic varices.

Esophageal Varices

The incidence of varices among all cirrhotic patients is around 50%. However, if monitored long enough, varices eventually develop in most cirrhotics.³⁷ Variceal hemorrhage occurs in a third of cirrhotic patients with varices. Although portal hypertension is defined by an HVPG greater than 5 mm Hg, Garcia-Tsao and colleagues showed that varices do not develop and hence do not bleed as long as the HVPG is less than 12 mm Hg.³⁸ However, once this threshold is reached, there is poor correlation between the pressure gradient and the risk for bleeding. Other risk factors associated with variceal bleeding include the degree of liver disease (provided by Child's classification), variceal location and size (higher risk near the gastroesophageal junction and with large varices), and the presence of particular endoscopic signs (red wale markings suggestive of dilated longitudinal venules, cherry-red spots, and hematocystic spots consisting of small red dots or a reddish blister-like formation on the variceal surface and the white or purple nipple sign on a varix) (Fig. 76.4).^{37,39}

Gastric Varices

Sarin and colleagues classified gastric varices into two groups: (1) isolated gastric varices (IGVs) and (2) gastroesophageal varices (GEVs) that are continuous with esophageal varices and extending to the cardia (GEV 1) or to the fundus (GEV 2).⁴⁰ The authors found that GEV 1 was the most common type of gastric varix but IGV was the type that bleeds the most. Although the incidence of bleeding from gastric varices is in the range of 10% to 36%, it is usually massive and associated with high mortality rates.⁴¹

DIAGNOSTIC EVALUATION

ENDOSCOPIC EXAMINATION

After the initial evaluation, resuscitation, and stabilization of a patient with upper GI bleeding, effort is directed at localization and treatment of the hemorrhage. Endoscopy has become the preferred diagnostic and therapeutic

Figure 76.4 A to C, Esophageal varices with red color and white nipple signs. (From Sheikh RA, Prindiville TP, Trudeau W: Gastrointestinal bleeding in portal hypertension. In DiMarino AJ, Benjamin S [eds]: *Gastrointestinal Disease: An Endoscopic Approach*, 2nd ed. Thorofare, NJ, Slack, 2002, pp 605-644.)

modality for upper GI bleeding because of its accuracy and low complication rate. With its use, a specific diagnosis can be achieved in 95% of patients. The use of promotility agents such as metoclopramide and intravenous erythromycin (250 mg by intravenous bolus or 3 mg/kg over a 30-minute period) before the endoscopic examination can significantly improve mucosal visibility by promoting gastric motility and emptying of gastric contents.⁴²⁻⁴⁴ An analysis of data from erythromycin trials showed that pre-endoscopic erythromycin was cost effective.⁴⁵

The optimal timing of endoscopy remains a balance between clinical need and resources and is still subject to controversy.²² Recent guidelines recommend the performance of upper endoscopy within 24 hours in patients with suspected nonvariceal upper GI bleeding.¹¹ Endoscopy has to be delayed or deferred in selected high-risk patients such as patients with bowel perforation or acute coronary syndrome. In a meta-analysis looking at timing of endoscopy, no significant reduction in rebleeding, surgery, or mortality rate was found with urgent endoscopy (1 to 12 hours)

compared with later endoscopy (more than 12 hours).¹¹ In a subset of patients with bloody gastric lavage, length of hospital stay and blood transfusion requirements were significantly lower in the urgent endoscopy group (within 12 hours).⁴⁶

One major role of endoscopy is to identify stigmata of recent hemorrhage known to correlate well with an increased risk for rebleeding and thus a need for endoscopic therapy. Rates of rebleeding with these specific endoscopic findings are summarized in [Table 76.5](#).⁴⁷

NONENDOSCOPIC ASSESSMENT

When endoscopy is not able to be performed or has not yielded a definitive diagnosis, angiography and radionuclide imaging may be useful alternatives. Such endoscopic failures are most often related to anatomic situations (i.e., strictures or surgical alterations) preventing full endoscopy. Esophagography and upper GI series are no longer used as part of the diagnostic evaluation of patients with upper GI bleeding.

Table 76.5 Stigmata of Ulcer Hemorrhage and Risk for Recurrent Bleeding without Endoscopic Therapy

Endoscopic Finding	Risk for Recurrent Bleeding without Therapy
Active arterial (spurting) bleeding	Approaches 100%
Nonbleeding visible vessel ("pigmented protuberance")	Up to 50%
Nonbleeding adherent clot	30-35%
Ulcer oozing (without other stigmata)	10-27%
Flat spots	<8%
Clean-based ulcers	<3%

From ASGE Standards of Practice Committee: ASGE guideline: The role of endoscopy in acute nonvariceal upper GI-hemorrhage. *Gastrointest Endosc* 1999;49:145-152; and from ASGE Standards of Practice Committee: ASGE guideline: The role of endoscopy in acute nonvariceal upper GI-hemorrhage. *Gastrointest Endosc* 1999;49:145-152.

THERAPEUTIC ALTERNATIVES

NONVARICEAL BLEEDING

Pharmacotherapy

Acid suppression has been shown to play a role in the inactivation of pepsin, optimization of platelet function, and inhibition of fibrinolysis. Subsequently, clot stabilization and ulcer healing may be more effective and rapid within a less acidic environment. This constitutes the rationale for acid suppressive therapy in patients with bleeding peptic ulcers.

Treatment with PPI before the performance of upper endoscopy has been shown to down-stage the endoscopic lesion and decrease the need for endoscopic intervention.¹¹ However, a meta-analysis including studies assessing oral, intravenous, and high-dose PPI failed to show significant differences in rates of mortality, rebleeding, or surgery between, the pre-endoscopic PPI therapy and control groups.⁴⁸

Once endoscopy is performed, the role of PPI therapy becomes more obvious. In patients found to have high-risk lesions treated endoscopically, an intravenous bolus followed by continuous-infusion PPI therapy is indicated.¹¹ The use of a continuous infusion is supported by data showing that maintenance of intragastric pH at greater than 6 after endoscopic hemostasis is associated with the lowest rebleeding rates and that this goal can be achieved only by bolus administration of a PPI followed by a constant infusion.⁴⁹ Strong data from several studies showed significant benefit in rebleeding, surgery, and mortality rates with high-dose intravenous PPI therapy after endoscopic treatment.⁵⁰ Other reports suggest similar benefits from low-dose intravenous and high-dose oral PPI therapy but these remain to be confirmed in larger studies.

Other agents with different mechanisms of action have been studied in patients with upper GI bleeding. A reduction in splanchnic blood flow with somatostatin and its analogs (such as octreotide) is an attractive measure in

patients with upper GI bleeding and has been the subject of several trials, with conflicting results.⁵¹⁻⁵³ To date, the available data are not convincingly in favor of using these agents in patients with nonvariceal upper GI bleeding, even though some authors find them useful in patients who are bleeding uncontrollably while awaiting endoscopy or surgery or in whom surgery is contraindicated.⁵¹

Endoscopic Therapy

Endoscopic therapy for nonvariceal upper GI bleeding in patients with high-risk lesions has been shown to reduce the rate of rebleeding, need for surgery, and mortality rate.⁵⁴ It is indicated in patients with active bleeding, spurting arterial vessels, and nonbleeding visible vessels in an underlying ulcer.⁴⁷ When a clot is found in an ulcer bed, targeted irrigation in an attempt at dislodgement with treatment of the underlying lesion is indicated. If the clot remains adherent after irrigation, endoscopic therapy (injection followed by snaring of the clot) may be considered but intensive PPI therapy alone may be sufficient.¹¹ Different forms of endoscopic therapy include injection technique, thermal technique, and mechanical technique. In many cases a combination of these modalities is used to treat a single bleeding lesion or one at high risk of bleeding.

Injection therapy results in hemostasis, probably from a combination of vascular tamponade and pharmacologic effect of the injected agent. Agents used for injection include normal saline solution, epinephrine, and sclerosants such as ethanol, ethanolamine, and polidocanol. In addition to the local tamponade effect of normal saline solution and epinephrine, the latter has a vasoconstricting effect. Sclerosant agents work by causing direct tissue injury and thrombosis.⁴⁷ Another class of agents used during injection therapy includes thrombin, fibrin, and cyanoacrylate glue. These agents create a primary tissue seal at the bleeding site. Epinephrine at a concentration of 1:10,000 or 1:20,000 is the most commonly used agent, sometimes in conjunction with other agents or techniques.

Thermal therapy consists of the delivery of heat to the mucosa, which results in edema, coagulation of tissue proteins, and contraction of arteries. When heat is delivered through a contact probe, an additional effect is achieved by mechanical compression of the target artery before delivery of the heat.

Thermal energy can be delivered through noncontact techniques such as the neodymium:yttrium-aluminum-garnet (Nd:YAG) and argon lasers and argon plasma coagulation (APC). The laser technique has been abandoned because of its high cost and the high risk of complications associated with its use. In APC, the argon gas forms a plasma and acts as an electrical conductor of the current, thereby resulting in coagulation of superficial tissues. Despite comparable results with the heater probe technique when used for ulcer bleeding,⁵⁵ APC is used primarily for the treatment of superficial lesions such as vascular abnormalities.⁴⁷

Contact thermal techniques refer to the delivery of heat through direct contact of the mucosa with heater probes or electrocautery probes (monopolar and bipolar probes). The heater probe is an aluminum cylinder that delivers a programmed amount of energy (heat) through its end or sides to the tissue. The catheter tip can also be used to apply firm pressure on the bleeding point or the visible vessel.

Electrocautery probes use an electrical current that passes from the electrode tip through the patient's body to a grounding plate (monopolar) or flows between two or more electrodes at the probe tip (bipolar or multipolar). The advantage of the bipolar (multipolar) probe is that the concentration of current at the level of the tip results in less depth of tissue injury and lower potential for perforation.

Mechanical therapy refers to the use of a device that causes physical tamponade of a bleeding site. Such devices include metallic clips, sewing devices, rubber band ligation, and endoloops. Metallic clips are the most studied of these devices and have shown variable success, probably because of the difficulty encountered with their placement. Some authors have suggested the use of clips in combination with other endoscopic treatments.⁵¹

The choice of endoscopic therapy depends on the stigmata of ulcer hemorrhage and the experience of the endoscopist. Monotherapy with epinephrine injection has been shown to be more effective than medical therapy in patients with high-risk lesions. However, it is inferior to other monotherapies (thermal or mechanical) or to combination therapy that uses two or more methods.¹¹ Epinephrine plus a second method significantly reduces rates of rebleeding, surgery, and mortality when compared to epinephrine alone.⁵⁶

Angiographic Therapy

Angiography can be useful as a potential diagnostic and therapeutic modality in specific cases of upper GI bleeding when endoscopy cannot be performed or fails to reveal the bleeding site and when endoscopic hemostasis is unsuccessful. It is also considered in patients who are poor surgical candidates.

Angiographic or "transcatheter" intervention in cases of upper GI bleeding involves two techniques: infusion of vasoconstricting medication and mechanical occlusion (embolization) of the arterial supply responsible for the hemorrhage. Vasopressin infusion induces vasoconstriction and results in cessation of bleeding in 70% to 80% of cases initially, but rebleeding occurs in up to 20%. Complications can range from problems related to arterial access to pulmonary edema and myocardial depression.⁵⁷ Vasopressin infusion has lost favor with the advent of embolization. Transcatheter embolization has become the mainstay for the radiographic treatment of nonvariceal upper GI bleeding and comes second after endoscopic therapy in most centers.⁵⁸ The embolic material used can be temporary (such as a gelatin sponge and autologous clot) or permanent (such as coils). Clinical success with embolization ranges from 52% to 91%. Potential complications of embolization include ischemia and perforation.⁵⁸

Surgical Therapy

When endoscopic hemostasis fails to control the bleeding or when hemorrhage recurs after successful control of bleeding, surgical intervention provides an alternative therapeutic option. The main goal of surgery is control of active bleeding and prevention of exsanguination, with a secondary aim to prevent recurrent ulceration. The choice of operation depends on the location of the bleeding lesion and the surgeon's expertise. Truncal vagotomy with antrectomy and vagotomy with pyloroplasty are examples of

operations performed in cases of nonvariceal upper GI bleeding. Total gastrectomy is rarely indicated. Because recurrent ulcers can be prevented by avoiding NSAIDs, eliminating *H. pylori* if present, or administering prophylactic PPI therapy, most ulcer operations for acute bleeding focus on oversewing the ulcer rather than performing the more definitive surgeries just listed.

VARICEAL BLEEDING

Pharmacotherapy

Pharmacologic agents used in the treatment of acute variceal bleeding are aimed at reducing portal pressure by either decreasing portal blood flow or reducing intrahepatic resistance. Infusion of vasoactive agents constitutes an adjunct to endoscopic therapy and often precedes endoscopy when suspicion of variceal bleeding is high.

Vasopressin, terlipressin, somatostatin, and somatostatin analogs (octreotide and lanreotide) all induce constriction of the splanchnic vasculature and result in a decrease in portal blood flow. Vasopressin causes systemic vasoconstriction, as well as splanchnic vasoconstriction, and can lead to adverse effects such as myocardial ischemia and infarction and cerebrovascular accidents.⁵⁹ These dangerous side effects led to the combination of vasopressin with other agents and the search for analogs with a better safety profile.

In one study, the combination of vasopressin with nitroglycerin resulted in a reduction in side effects and improved efficacy over vasopressin alone.⁵⁹ Nitroglycerin, a potent venous dilator, decreases the hemodynamic side effects of vasopressin and at the same time reduces intrahepatic resistance, thereby resulting in a further reduction in portal pressure.

Terlipressin is a synthetic analog of vasopressin with a longer duration of action and fewer side effects than vasopressin. Unlike other vasoactive agents, terlipressin has been shown to reduce mortality rate when compared with placebo.⁶⁰ At present, terlipressin is not available in the United States.

Somatostatin is a naturally occurring peptide that induces splanchnic vasoconstriction without affecting the systemic circulation and thus results in a decrease in portal pressure. When compared with vasopressin, somatostatin was equivalent in bleeding control but had significantly fewer side effects.⁶¹ Further data suggested that somatostatin has the greatest effect when used in conjunction with endoscopic therapy.^{62,63} Octreotide, a somatostatin analog, is approved for use in variceal bleeding in the United States. Meta-analyses looking at the efficacy of octreotide led to controversial results.^{61,64} One meta-analysis of trials of somatostatin analogs in general showed a negligible effect.⁶⁵ However, octreotide appears to be useful as an adjunct to endoscopic therapy.^{66,67} At present, because of its excellent safety profile and easy availability, octreotide (50- μ g bolus followed by a 50- μ g/hour continuous infusion for 3 to 5 days) is almost always used in conjunction with endoscopic therapy.

The use of prophylactic antibiotics in patients with variceal bleeding has been shown to decrease the mortality rate in several randomized controlled trials.⁶² The rationale behind antibiotic prophylaxis derives from the fact that bacterial infection is present in up to 20% of patients with cirrhosis who are admitted with variceal bleeding and that

infection develops in as many as 50% of patients while hospitalized.⁶⁸ The mortality rate is significantly higher in infected cirrhotic patients than in noninfected cirrhotics.^{69,70} Furthermore, infected cirrhotic patients have a higher rate of variceal rebleeding.⁷¹ This is probably due to the presence of cytokines and endotoxins that induce hematologic abnormalities such as platelet dysfunction and activation of the coagulation and fibrinolytic systems.⁶² A recently updated meta-analysis showed that antibiotic prophylaxis significantly reduced the all-cause mortality rate, bacterial infection mortality rate, rebleeding events, and length of hospital stay.⁷² Prophylaxis benefits were observed regardless of the type of antibiotic used. Nonabsorbable antibiotics, quinolones, and more recently cephalosporins have all been used with good success. Recent concerns have been raised about bacterial resistance and potential decreased benefit with quinolones in some geographic areas.⁷²

The use of recombinant factor VIIa in cirrhotic patients with upper GI bleeding has been attractive because cirrhotic patients will often have deficiencies in coagulation factors and factor VII in particular. In a randomized controlled trial investigating the use of this factor, Bosch and coworkers⁷³ demonstrated benefit in the rate of rebleeding only in the subgroup of patients with advanced cirrhosis (Child-Pugh grades B and C). A 2010 retrospective study (Flower and colleagues) showed no benefits in mortality rate reduction when recombinant factor VII was used in patients with upper GI bleeding.⁷⁴ Further studies are needed before the routine use of this expensive therapy can be recommended.

Endoscopic Therapy

Endoscopic sclerotherapy and endoscopic band ligation are the mainstays of therapy for acute variceal bleeding. These procedures are successful in achieving hemostasis in 80% to 90% of patients.⁶²

Sclerotherapy consists of intravariceal or paravariceal injection of a sclerosant agent such as sodium tetradecyl sulfate or ethanolamine. These agents provoke a severe inflammatory reaction within or around the varix that leads to variceal thrombosis and obliteration. Despite its high effectiveness in controlling bleeding, the complication rate with sclerotherapy can be as high as 40%.⁷⁵ Complications range from local effects, such as deep ulcers causing rebleeding, odynophagia, and in some cases perforation to bacteremia and systemic complications such as pleural and pericardial effusion. Esophageal stricture is the most common long-term side effect of sclerotherapy. Once the acute bleeding is controlled, repeated sessions of sclerotherapy are required to eradicate the varices and prevent rebleeding.

Endoscopic band ligation consists of the placement of a ligating device on the tip of the endoscope, and elastic rings are placed over the targeted varix (Fig. 76.5). With the availability of multiband ligating devices, 5 to 10 bands can be deployed in one session. Band ligation has a lower rate of complication (including the rebleeding rate in some but not all studies⁷⁶) than sclerotherapy does, but it can be difficult to perform during acute bleeding.⁶² Superficial mucosal ulceration occurs when the elastic ring and underlying tissue slough off. Transient chest discomfort and dysphagia are common after band ligation. Band ligation also

Figure 76.5 Esophageal varices immediately after band ligation. (From Bashir RM, Al-Kawas FH: Vascular lesions of the stomach. In DiMarino AJ, Benjamin S [eds]: *Gastrointestinal Disease: An Endoscopic Approach*, 2nd ed. Thorofare, NJ, Slack, 2002, pp 245-262.)

has the advantage of achieving eradication of varices with fewer endoscopic sessions than are typically needed for sclerotherapy.⁷⁶

A meta-analysis of 10 randomized clinical trials showed an almost significant benefit of endoscopic band ligation over sclerotherapy in the initial control of bleeding.⁷⁷ A practice guideline by the American Association for the Study of Liver Diseases recommends the use of endoscopic band ligation as the preferred form of endoscopic therapy and the use of sclerotherapy when band ligation is not technically feasible.⁶⁷

Balloon Tamponade

The use of balloon tamponade in the control of active variceal bleeding comes as a last resort when other forms of therapy are not available or fail to achieve hemostasis. Three balloons have been used for this purpose: the Minnesota tube, the Sengstaken-Blakemore tube, and the Linton-Nachlas tube. Control of bleeding with these tubes depends on patient selection, the concomitant use of other therapies, and the experience of the staff using them. With the advent of other therapies and the increasing experience of endoscopists in sclerotherapy and endoscopic banding, experience in the use of tamponade balloons decreased substantially. A major concern with the use of these tubes is the high risk of rebleeding after deflation of the balloon, in addition to the risk of esophageal rupture. Balloon tamponade should be used only as a temporary means of stabilization and as a bridge to a more definitive form of therapy. Figure 76.6 illustrates the steps used to control bleeding with a balloon. The use of a fully covered self-expandable metallic stent has shown some promise in control of variceal bleeding.⁷⁸

Transjugular Intrahepatic Portosystemic Shunt

The transjugular intrahepatic portosystemic shunt (TIPS) procedure involves the creation of a low-resistance channel between the portal vein and the hepatic vein through which blood is shunted from the portal to the systemic circulation.

Figure 76.6 Sengstaken-Blakemore tube. The tube is passed to at least the 50-cm mark. The gastric balloon is then inflated with the full recommended volume of air (usually 450-500 mL). Portable chest radiograph should be obtained to check for proper placement. The tube is pulled back gently until resistance is felt against the diaphragm. If bleeding persists from the aspiration port, the esophageal balloon is inflated to the lowest pressure needed to stop bleeding (usually 30-45 mm Hg).

Via an angiographic technique, an expandable metal stent is deployed across this channel and results in a significant decrease in portal pressure. This technique allows the creation of a portosystemic shunt without requiring general anesthesia and major surgery. TIPS is indicated in situations in which acute variceal bleeding is refractory to endoscopic and pharmacologic therapy. It has been shown to control bleeding in more than 90% of patients, with a rebleeding rate of less than 20%.^{79,80} In 2010 data (Garcia-Tsao and colleagues) showed that early TIPS (within 24 to 48 hours of admission) was associated with significant decrease in mortality rate in high-risk patients (with HVPG >20 mm Hg or with Child-Pugh class C disease).⁸¹ However, the mortality rate after the TIPS procedure in the setting of acute uncontrollable variceal bleeding is between 30% and 40%.⁶² A major complication associated with this procedure is the development of encephalopathy in 10% to 20% of patients. Stenosis and complete occlusion of the shunt occur in 5% to 15% of the cases, requiring revision.

Surgical Therapy

Surgical creation of portosystemic shunts has been used for decompression of the portal system to treat and prevent variceal bleeding. The various forms of surgical shunts include portacaval shunts, distal splenorenal shunts, and partial shunts. Revascularization of the esophagus is another surgical option for the treatment of variceal bleeding. Interest in surgery has declined over the years because of the advent of the less invasive endoscopic and TIPS procedures. At present, surgery is considered only when medical and endoscopic therapy fails to control bleeding and TIPS is not available.⁶²

STRESS-RELATED MUCOSAL DISEASE

The term *stress-related mucosal disease* (SRMD) covers a spectrum of conditions ranging from superficial mucosal damage to focal deep mucosal damage (stress ulcers). The terms *stress ulcer*, *stress gastritis*, *stress erosions*, and *stress lesions* are used interchangeably in the literature. SRMD is defined as mucosal abnormalities of the upper GI tract that occur with extreme physiologic stress, typically in the ICU.

The incidence of endoscopically documented gastric lesions in patients in the ICU ranges from 74% to 100%.⁸² The lesions are typically, but not exclusively, located in the fundus and body of the stomach. However, most of these lesions are of little significance because healing occurs rapidly. Clinically evident bleeding, defined as blood in a nasogastric aspirate, hematemesis, and melena, occurs in 5% to 25% of patients in the ICU. Clinically important bleeding, however, is defined as overt bleeding associated with one of the following within 24 hours of the onset of the bleeding: a drop in systolic blood pressure of greater than 20 mm Hg, an increase in the pulse rate of more than 20 beats per minute and a 10-mm Hg drop in systolic blood pressure, or a decrease in hemoglobin of greater than 2 g/dL requiring blood transfusion and failure of hemoglobin to increase by the number of units transfused minus 2 g/dL.⁸³ Clinically important bleeding affects only 3% to 6% of critically ill patients.⁸⁴

The pathogenesis of SRMD involves a disruption in the balance between aggressive and protective factors that leads to gastric mucosal damage. Adequate microcirculation in the upper GI tract is the most important defense mechanism against luminal aggressors such as acid and enzyme secretion, as well as infection. The role of the microcirculation is to provide nutrients and eliminate toxic oxygen-derived free radicals. In the presence of severe physiologic stress, disruption of intramucosal blood flow leads to a number of events, including the formation of toxic oxygen-derived radicals, a decrease in the synthesis of cytoprotective prostaglandins and mucus production, and a reduction in bicarbonate secretion resulting in an increase in intramural acidity (Fig. 76.7).^{82,84} These events create a favorable setting for mucosal injury and ulceration.^{85,86} Subsequent reperfusion also plays a major role in the development of lesions.⁸⁶

Identification of critically ill patients at risk for significant bleeding from SRMD has been the subject of several studies. A landmark study by Cook and associates⁸³ demonstrated a

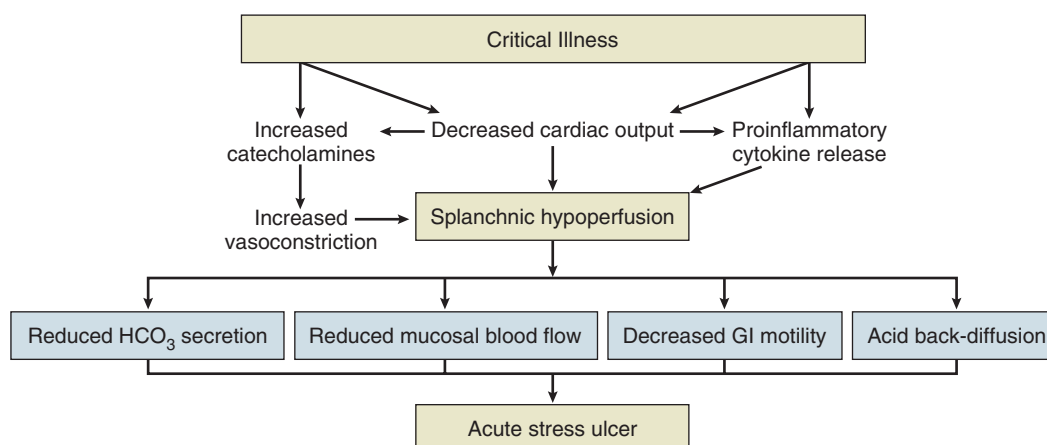

Figure 76.7 Pathophysiology of stress ulcers. (From Mutlu GM, Mutlu EA, Factor P: GI complications in patients receiving mechanical ventilation. *Chest* 2001;119:1222-1241.)

significant increase in the risk for bleeding from SRMD in patients requiring mechanical ventilation for more than 48 hours and in those with coagulopathy (defined as thrombocytopenia [platelet count $<50,000/\text{mL}^3$], an international normalized ratio above 1.5, or a partial thromboplastin time more than 2.0 times the control value). Other risk factors such as shock, sepsis, renal failure, liver failure, and glucocorticoids were identified, but the association with bleeding was not statistically significant. Risk factors associated with the presence of SRMD (not necessarily bleeding) include recent major surgery, major trauma, severe burns (Curling's ulcers), head trauma or coma (Cushing's ulcers), and multiple organ failure.⁸⁷⁻⁸⁹ Further understanding of the risk factors associated with bleeding from SRMD will help in directing prophylactic therapy to patients who will benefit most from this therapy.⁹⁰

The reported mortality rates in critically ill patients with bleeding from SRMD ranges from 46% to 77%.^{83,91,92} These high rates are most likely due to the underlying disease and not directly related to GI bleeding. However, they reveal the importance of significant bleeding as a sign of the degree of severity of the primary illness.

PROPHYLAXIS

As mentioned earlier, the risk for bleeding from SRMD is significantly increased in patients undergoing prolonged mechanical ventilation and in those with coagulopathy. Such patients should benefit from the different forms of prophylaxis available.

The role of enteral nutrition in prophylaxis for SRMD is controversial.^{93,94} The rationale behind the use of enteral nutrition derives from its ability to improve blood flow to the stomach and sustain mucosal immunity and integrity.⁹⁵ However, experimental data in hemodynamically compromised animals showed an increase in tissue hypoxia when enteral nutrition was administered.⁹⁶ Furthermore, in one study the degree of acid suppression was reduced in patients receiving H_2 receptor antagonists (H_2 RAs) or PPIs with concomitant enteral feeding.⁹⁷

When compared with placebo, antacids have been shown to decrease bleeding in patients with SRMD.⁹⁸ However, antacids require frequent dosing and monitoring of pH and

are not practical to use, especially with the advent of other effective agents for prophylaxis.

Sucralfate works by coating the gastric mucosa and forming a thin protective layer between the mucosa and the gastric acid in the lumen without affecting acid secretion and intragastric pH. The use of sucralfate for the prevention of bleeding in patients with SRMD gained interest because of theoretical concern about gram-negative bacterial overgrowth when the pH of the stomach is increased by the use of H_2 RAs or PPIs, which can potentially lead to nosocomial pneumonia. Conflicting results were reported regarding this issue, but a large trial by Cook and colleagues in which ranitidine and sucralfate were compared showed no significant difference in the development of nosocomial pneumonia.⁹⁹ In this same trial, the incidence of clinically important bleeding was significantly lower with ranitidine. Other studies demonstrated comparable efficacy between sucralfate and antacids and H_2 RAs in terms of prevention of SRMD.^{100,101} One drawback to the use of sucralfate is that it may decrease the absorption of other concomitantly administered oral drugs.

Intravenous H_2 RAs are the most widely used pharmacologic agents for the prophylaxis of bleeding in patients with SRMD. A meta-analysis of studies looking at the role of H_2 RAs in SRMD demonstrated a decrease in the incidence of clinically important bleeding.⁹⁸ Furthermore, H_2 RAs were more effective than antacids in preventing bleeding.^{98,102} Despite better control of gastric pH with continuous infusion of H_2 RAs, bolus infusion has been shown to be as effective in preventing bleeding.^{98,103} One major concern is the development of tolerance to H_2 RAs when administered for a prolonged period.

In recent years PPIs have gained wider use in the prevention of bleeding from SRMD because of their ease of dosing, effective and predictable acid suppression, lack of need for regular gastric pH monitoring, and lack of tolerance as encountered with H_2 RAs.⁹⁵ A recent meta-analysis compared the efficacy of PPIs versus H_2 RAs in the prophylaxis of stress-related mucosal bleeding in critically ill patients at risk of bleeding. It demonstrated that PPI prophylaxis significantly decreased rates of clinically significant bleeding compared with H_2 RAs without affecting the development of nosocomial pneumonia or mortality rates.¹⁰⁴

TREATMENT

Endoscopy is the principal diagnostic and therapeutic procedure used in patients with bleeding from SRMD. The same endoscopic techniques used for hemostasis in peptic ulcer bleeding are used in SRMD when an actively bleeding lesion is found. Surgery is reserved for patients with uncontrolled hemorrhage and usually involves vagotomy, oversewing of bleeding sites, and in rare cases, subtotal or total gastrectomy.⁹⁵ In poor surgical candidates with severe uncontrolled hemorrhage, angiography may be a useful diagnostic and therapeutic option.

LOWER GASTROINTESTINAL BLEEDING

DIFFERENTIAL DIAGNOSIS

Lower GI bleeding is defined as bleeding that originates from a source distal to the ligament of Treitz. It is caused by a diverse range of bleeding sources and can range from trivial to life-threatening bleeding. It can also be acute, arbitrarily defined as less than 3 days' duration and possibly resulting in hemodynamic compromise, or chronic, extending over a period of several days or longer and usually less severe in terms of the amount of blood loss.¹⁰⁵ Sources of lower GI bleeding and their incidence from several large studies are listed in Table 76.6.¹⁰⁶⁻¹¹³

DIVERTICULAR BLEEDING

Diverticular bleeding, the most common source of lower GI bleeding, accounts for up to 40% of cases.¹⁰⁵ Diverticular disease is more common in the elderly. It affects up to two thirds of people older than 80 years. Only 3% to 15% of patients with diverticulosis experience diverticular bleeding.¹⁰⁵

Patients with diverticular bleeding typically have painless hematochezia. Most patients will stop bleeding spontaneously, but the bleeding can recur in 10% to 40% of cases.¹¹⁴

The bleeding is thought to occur after repetitive trauma to the vasa recta (nutrient arteries) that stretch over the diverticular dome.¹¹⁵ NSAIDs have been associated with increased risk for diverticular bleeding.¹¹⁶

ISCHEMIC COLITIS AND OTHER FORMS OF COLITIS

Ischemic colitis accounts for up to 19% of lower GI bleeding.¹⁰⁵ It results from a sudden reduction in mesenteric blood flow. As opposed to acute mesenteric ischemia, this reduction is transient and reversible. The typical regions affected are the "watershed" areas of the colon: the splenic flexure, the rectosigmoid junction, and the right colon. Ischemia is precipitated by any event that compromises colonic blood flow. Clinically, patients have a sudden onset of abdominal pain, followed by hematochezia within 24 hours. Endoscopically, ischemia is suspected in the presence of bluish hemorrhagic nodules from submucosal bleeding, cyanotic or necrotic mucosa with hemorrhagic ulcerations, or segmental distribution with an abrupt transition between injured and normal mucosa (Fig. 76.8).¹⁰⁵ Most cases of ischemic colitis resolve spontaneously with supportive treatment. Rare cases require surgery (if peritoneal signs are present) or develop chronic ischemic colitis with stricture formation. Ischemic colitis is a common cause of lower GI bleeding in patients in the ICU because of the frequent hemodynamic instability in this setting.¹¹⁷

Infectious colitis, radiation colitis, and inflammatory bowel diseases can also result in bloody diarrhea, but the bleeding is rarely severe.

ANGIODYSPLASIA

Estimates of angiodysplasia as a source of lower GI bleeding vary widely and reach 37% in some reports.¹⁰⁸ Current data suggest that acute bleeding caused by angiodysplasia is less

frequent than previously thought, with most cases demonstrating iron deficiency anemia and occult blood loss.¹¹⁵ These lesions are seen predominantly in the elderly. They appear endoscopically as red, flat lesions with ectatic blood vessels radiating from a central feeding vessel, usually in the right colon (Fig. 76.9). Overt bleeding from angiodysplasia is usually brisk and painless and cannot be distinguished from diverticular bleeding. Endoscopic treatment is highly effective and safe and prevents bleeding episodes from recurring.

OTHER SOURCES OF LOWER GASTROINTESTINAL BLEEDING

Acute significant bleeding from colonic neoplasia and polyps is uncommon despite reports in which it accounts for up to 36% of cases.¹¹² Cancer and polyps are thought to bleed from erosions on the surface.

Postpolypectomy bleeding occurs in 1% to 6% of patients undergoing colonoscopic polypectomy.¹¹⁵ Bleeding can be immediate or delayed up to 3 weeks after the procedure. Risk factors for postpolypectomy bleeding include large size, sessile morphologic appearance, and right colonic location.¹¹⁸

Anorectal sources of lower GI bleeding include hemorrhoids, anorectal fissures, stercoral ulcers, and proctitis. Hemorrhoids can cause significant bleeding and may sometimes require endoscopic or surgical intervention. Bleeding from rectal ulcers is common in elderly bedridden patients and in critically ill patients.¹⁰⁶

Small bowel sources of lower GI bleeding include angiodysplasia (most frequent), lymphoma, small bowel ulcers, and Crohn's disease.¹¹⁵ Small bowel lesions are typically more difficult to identify and require more diagnostic procedures.¹¹⁹

DIAGNOSTIC EVALUATION

COLONOSCOPY

After initial evaluation, stabilization, and exclusion of an upper GI source, management shifts to localization of the lower GI bleeding site. Colonoscopy is an attractive choice in this setting because it offers the best opportunity for early diagnosis and subsequent management. In the past, colonoscopy used to be performed in an expectant manner, after cessation of bleeding and colonic preparation. Concern about poor visibility, the potential for complications, and the adverse effects of bowel preparation in the setting of bleeding is behind the reluctance in performing “urgent” colonoscopy. Over the past decade, early colonoscopy has gained interest in the management of lower GI bleeding. Several reports have shown that early (or urgent) colonoscopy is safe and has high diagnostic yield in patients with hematochezia.¹²⁰⁻¹²⁴ The definition of “urgent” varied in these reports, from within 8 hours to within 24 hours of initial evaluation. This approach was also associated with shorter hospital stay.¹²⁵ Bowel preparation is generally recommended before urgent colonoscopy to improve visibility and prevent complications related to poor visibility. Polyethylene glycol lavage solution by mouth or through a nasogastric tube is commonly used in these cases. It can be administered at a rate of approximately 1 L every 30 to 45 minutes.¹⁰⁵ Some authors have proposed the use of colonoscopy without bowel preparation and have shown high diagnostic yield with this approach.¹²⁶ Despite the fact that urgent colonoscopy improves the diagnostic yield and leads to more frequent endoscopic therapy, there is still controversy regarding its impact on important outcomes such as mortality rate, rebleeding, and the need for surgery.^{122,124} Jensen and colleagues¹²² showed that urgent colonoscopy with endoscopic treatment in a group of patients with active diverticular bleeding (versus a historical group that did not receive endoscopic treatment) may prevent recurrent bleeding and the need for surgery. Another randomized trial compared urgent colonoscopy with a standard care algorithm in which radionuclide scanning, followed, if positive, by angiography, was used in patients with suspected active bleeding versus expectant colonoscopy in those without active bleeding. This trial showed that a definite source of bleeding was found more often in urgent colonoscopy patients. However, no difference in mortality rate, surgery, and rebleeding was found in the two groups.¹²⁴ A more recent trial looking at the benefit of urgent versus elective colonoscopy (<12 hours vs. 36 to 60 hours from presentation) showed no evidence of improving clinical outcomes such as rebleeding, transfusion requirements, and hospital length of stay. A major limitation of this trial was that the study was terminated before reaching the prespecified sample size.¹²⁷ In conclusion, the optimal timing of colonoscopy in patients with lower GI bleeding has not been determined and it is unknown if early performance of colonoscopy affects major outcomes such as rebleeding and mortality rate.¹⁵

RADIONUCLIDE SCANNING

The use of radionuclide scanning (also known as a technetium-labeled red blood cell scan) in patients with

lower GI bleeding is highly controversial. It has been used for several decades as a method for localization of the bleeding source.¹¹⁵ A main advantage of radionuclide scanning is its sensitivity for bleeding at a rate as low as 0.05 to 0.1 mL/minute, in addition to its noninvasive nature.¹¹⁵ It also can be repeated in cases of intermittent bleeding. On the other hand, this diagnostic modality lacks therapeutic capability, has variable accuracy, and may delay other diagnostic and therapeutic procedures. A review of data from several studies of radionuclide scanning for lower GI bleeding in which radionuclide scintigraphy findings were confirmed by a different test found the accuracy of a positive test to be 66%.¹⁵ Localization improves when scans are positive within 2 hours of injection. A common practice in the setting of ongoing lower GI bleeding is to perform radionuclide scanning as a screening test before angiography and in some cases as a guide to surgery. The problem with this approach is the inconsistent and widely variable accuracy and the high rate of false-positive results in different reports.^{115,128,129}

ANGIOGRAPHY

Angiography is less sensitive than radionuclide scanning in the detection of active bleeding. It can detect bleeding at a rate of 0.5 to 1.0 mL/minute. In addition to its role in accurate localization of bleeding lesions, angiography offers therapeutic possibilities. As with radionuclide scanning, the ability of angiography to detect the bleeding source varies widely among studies, from 20% to 70%.¹¹⁵ This variation is due to several factors, including patient selection (higher diagnostic yield in patients with positive radionuclide scanning), the severity and intermittent nature of the bleeding, procedural delay, and venous or small vessel bleeding.¹¹⁵ In one study, a systolic blood pressure of less than 90 mm Hg and a requirement of at least 5 units of blood within a 24-hour period have been shown to predict a positive angiography (85% when both criteria were present).¹³⁰ Angiography is usually performed in patients with ongoing lower GI bleeding with or without a positive radionuclide scan. This sequence in management was the standard approach to ongoing bleeding up until recently, when colonoscopy started gaining interest in the setting of acute bleeding (as opposed to expectant elective colonoscopy). When angiographic therapy fails or is not available after localization of the bleeding, the findings are used to guide surgical resection. Angiography can cause serious complications such as contrast reactions, arterial thrombosis and dissection, and catheter site infection and bleeding. Thus, it should be used in carefully selected patients.

COMPUTED TOMOGRAPHY

CT gained interest in the setting of GI bleeding after the recent introduction of multidetector row CT. It enables the accurate acquisition of arterial images, which can show contrast extravasation in areas of active bleeding.¹⁵ It can detect bleeding rates as low as 0.3 to 0.5 mL/minute. The yield for lower GI bleeding ranges from 25% to 95% and is highest in severe ongoing bleeding. The advantages of CT are its wide availability and the added diagnostic yield of cross-sectional imaging, but exposure to radiation and contrast and, like radionuclide scanning, the inability to deliver

therapy constitute some of the disadvantages of this technique.¹⁵

THERAPEUTIC ALTERNATIVES

ENDOSCOPIC THERAPY

Data on the effectiveness of endoscopic therapy for lesions causing lower GI bleeding are limited. However, the experience from published series suggests that this form of therapy is likely to be beneficial. Methods of endoscopic hemostasis are similar to those used for upper GI bleeding and include injection therapy, thermal therapy (APC and heater and electrocautery probes), and mechanical therapy (hemoclips).¹³¹ Several studies showed that clipping is very effective modality for diverticular bleeding with a low rate of early rebleeding.¹⁵

ANGIOGRAPHIC THERAPY

When angiography identifies the bleeding site in cases of lower GI bleeding, hemostasis can be achieved by the intra-arterial infusion of vasopressin or superselective embolization. Infusion of vasopressin can control bleeding in up to 91% of cases,¹³¹ but complications develop in 10% to 20% and include arrhythmia, pulmonary edema, and ischemia.¹³¹ Furthermore, rebleeding occurs in as many as 50% of cases.¹³¹ In early studies, transcatheter embolization carried a high risk for bowel infarction, but current superselective techniques using smaller catheters with various agents (gelatin sponge, microcoils, and polyvinyl alcohol particles) appear to be more effective and safer than the old techniques. Review of several studies using superselective techniques showed that immediate hemostasis was achieved in 96% of cases and rebleeding within 30 days occurred in 22%.¹⁵ Since the advent of these new techniques, embolization has become the preferred modality when angiographic therapy is contemplated.

SURGICAL THERAPY

Surgery is indicated in cases of recurrent bleeding (especially diverticular) and massive ongoing bleeding with high transfusion requirements (generally more than 6 units of packed red blood cells in a 24-hour period).¹⁰⁵ Accurate localization of the site of bleeding preoperatively is crucial so that segmental rather than subtotal colectomy can be performed. Unfortunately, the accuracy of radionuclide scanning in localization of the bleeding is variable, and hence it should not be used as a guide for surgery. Colonoscopy and angiography may be used as a guide for surgery in cases in which bleeding is initially identified and possibly treated through these modalities and then recurs and requires surgery.

OBSCURE GASTROINTESTINAL BLEEDING

Obscure GI bleeding is bleeding that persists or recurs without an obvious source identified on upper and lower endoscopy. Obscure bleeding can be occult (positive fecal occult blood testing without frank recognizable blood loss) or overt (clinically evident). Obscure bleeding can be very challenging to the physician and, in cases of overt massive

bleeding, life-threatening to the patient. The initial approach to the problem is the same as with upper and lower GI bleeding and includes resuscitation and stabilization, followed by a search for the source.

DIFFERENTIAL DIAGNOSIS

Missed lesions on upper and lower endoscopy should be considered first in the workup of obscure bleeding. Causes difficult to identify on routine endoscopy include hemosuccus pancreaticus, hemobilia, aortoenteric fistula, Dieulafoy's ulcer, and extraesophageal varices. Small bowel lesions are another source of obscure bleeding and include tumors (lymphomas, carcinoids, adenocarcinomas), vascular ectasia, NSAID-induced ulcers, Meckel's diverticulum, and other less common causes.¹³²

DIAGNOSTIC EVALUATION

Repeat upper and lower endoscopy is usually warranted at least once after the index endoscopy, with the uncommon and subtle lesions just listed kept in mind. When the patient has active ongoing bleeding, radionuclide scanning and angiography should be considered. In young patients, Meckel's diverticulum scan may be helpful. If all these tests are negative, the focus should shift to evaluation of the small bowel. Radiographic, endoscopic, and surgical modalities are used for this purpose.

Small bowel follow-through (SBFT) and enteroclysis (which is a modified form of SBFT) should be performed only when Crohn's disease or malignancy is suspected. These modalities have lost favor with the advent of capsule endoscopy and device-assisted enteroscopy (except in cases in which there may be narrowing of the small bowel). Small bowel push enteroscopy can be very helpful in identifying and, in some cases, treating lesions in the small bowel that are responsible for obscure bleeding. Unfortunately, it can examine only 50 to 150 cm of small bowel.¹³³ Device-assisted enteroscopy (double and single balloon enteroscopy and spiral enteroscopy) has comparable diagnostic yield to capsule endoscopy but has the advantage of performing therapeutic interventions and obtaining biopsies.¹³⁴

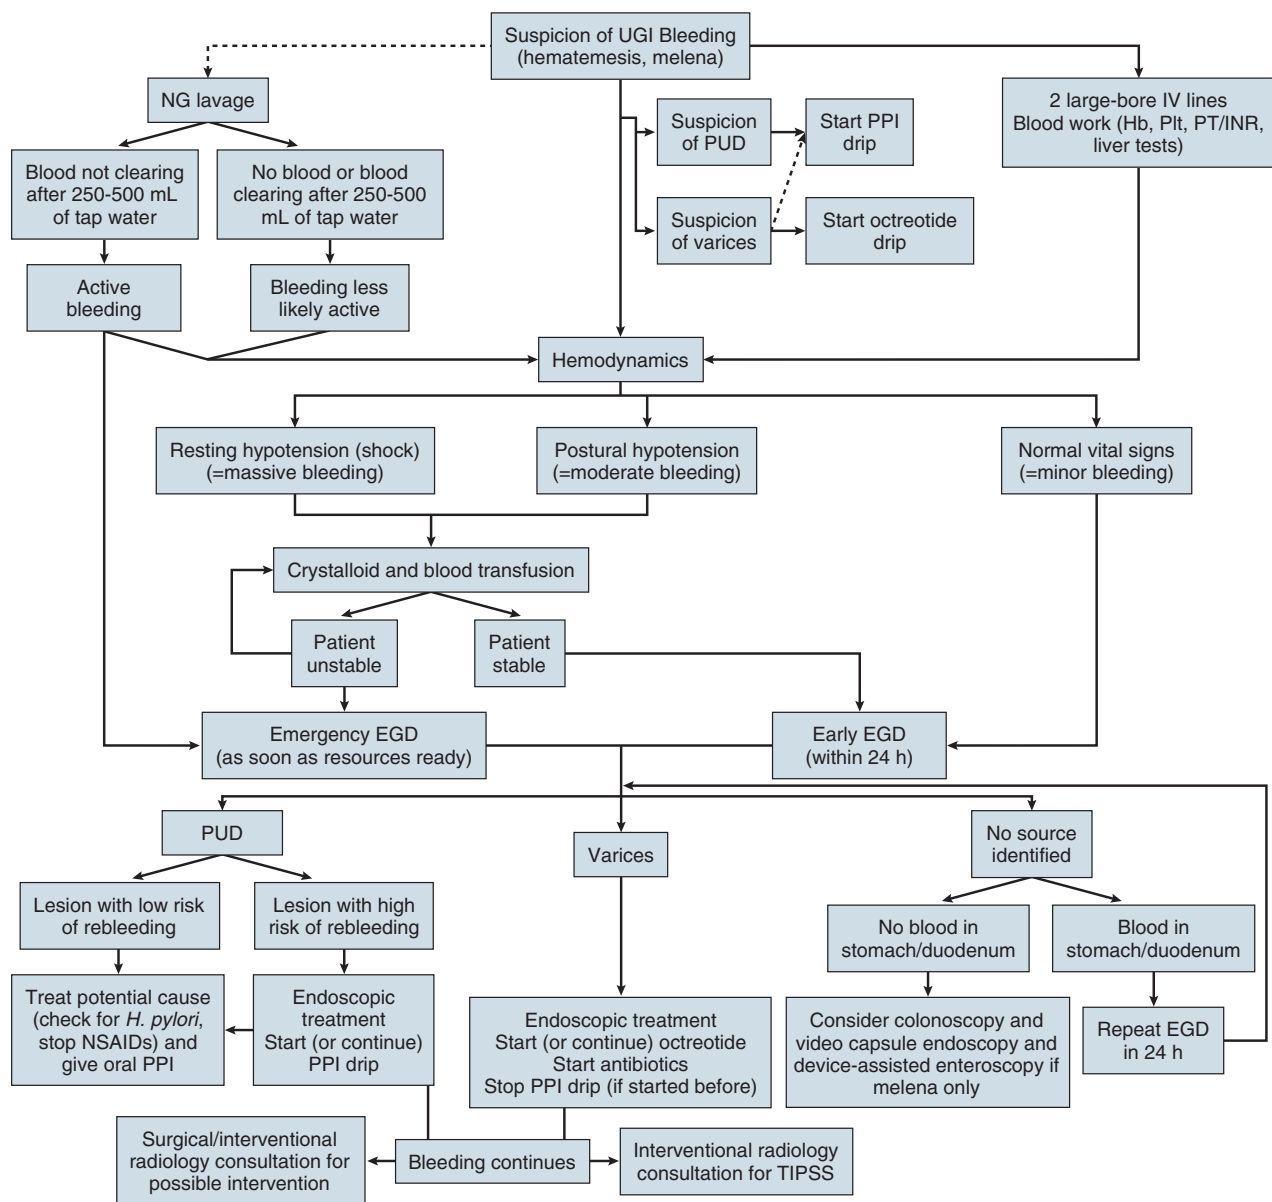

Capsule endoscopy gained large interest in evaluation of the small bowel because of its ability to examine the entire small bowel and its noninvasive nature. It consists of swallowing a pill-sized camera with sufficient battery life to image the entire small bowel. Studies have supported the role of capsule endoscopy in the evaluation of obscure GI bleeding with an overall diagnostic yield of 55% to 70%.¹³² The diagnostic yield is even higher when it is administered to patients with ongoing bleeding (87% to 92%).^{135,136} In our opinion, efforts should be made to perform capsule endoscopy in patients with obscure overt bleeding while still in the hospital instead of waiting until discharge (which is the current standard practice in most centers). In patients who can tolerate an invasive procedure, device-assisted enteroscopy can be used when available and has the advantage of therapeutic ability. However, this procedure only achieves total enteroscopy in 29% of patients. Other limitations include limited availability, time, and sedation requirements. The procedure's risk of complications is low (less than 1%).¹³⁴

Exploratory laparotomy is generally the last option in the evaluation of obscure GI bleeding. When combined with intraoperative enteroscopy, the diagnostic yield reaches 50% to 100%.¹³²

CONCLUSION

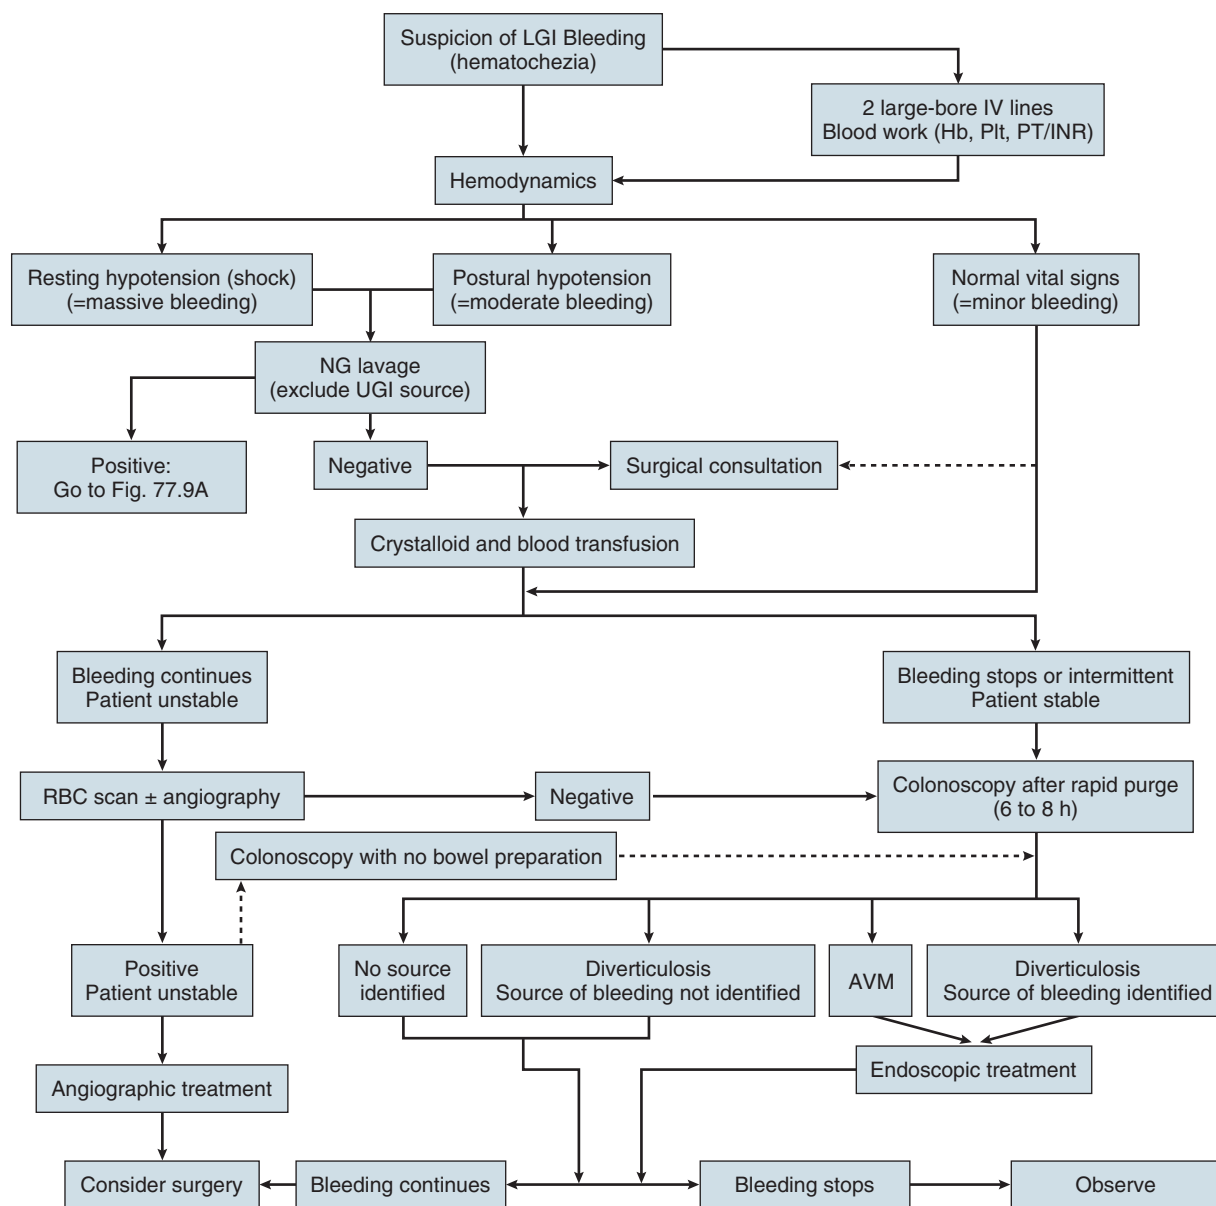

In summary, acute GI bleeding is a life-threatening emergency that requires a quick response and a coordinated team approach. Acute management is the same regardless

of the source of bleeding (Fig. 76.10) and should be orchestrated by a critical care team. The prime direction in resuscitation should be restoration of euvolemia. Once a source is suspected, specific management and therapeutic options are considered and may require communication with gastroenterologists, surgeons, and interventional radiologists. Prevention of bleeding from SRMD is indicated in a specific population of critically ill patients. Endoscopy plays a major role in the diagnosis and management of acute GI bleeding. Endoscopic therapy with standard and innovative techniques has been shown to have a major impact on the prognosis of bleeding patients.

B

Figure 76.10, cont'd B, Approach to managing lower gastrointestinal bleeding in critical care patients. AVM, arteriovenous malformation; EGD, esophagogastroduodenoscopy; Hb, hemoglobin; INR, international normalized ratio; LGI, lower gastrointestinal; NG, nasogastric; NSAIDs, nonsteroidal anti-inflammatory drugs; Plt, platelets; PPI, proton pump inhibitor; PT, prothrombin time; PUD, peptic ulcer disease; RBC, red blood cell; TIPSS, transjugular intrahepatic portosystemic stent shunt; UGI, upper gastrointestinal.

KEY POINTS

- The history gives important clues regarding the cause of the acute GI bleeding and helps direct initial management.
- Management of GI bleeding relies on a team approach involving an intensivist, endoscopist, radiologist, and surgeon.
- The prime direction of evaluation and resuscitation in a bleeding patient should be restoration of euvolemia.
- SRMD is a common source of upper GI bleeding in physiologically stressed patients, and prophylaxis with acid suppressants should be given to patients with coagulopathy and those undergoing prolonged mechanical ventilation.
- PPIs in drip form should be given to patients with upper GI bleeding after endoscopic treatment of lesions with a high risk of rebleeding.
- Antibiotic therapy decreases the mortality rate in patients with variceal bleeding. It should be given empirically along with vasoactive agents (octreotide).
- Several forms of endoscopic therapy are effective for nonvariceal bleeding, including injection, thermal, and mechanical therapy.
- Endoscopic band ligation is the most commonly used and preferred technique for the treatment of bleeding varices.
- Early colonoscopy has become an attractive choice in lower GI bleeding because of its diagnostic and therapeutic abilities.
- Videocapsule endoscopy has an important role in the evaluation of patients with obscure overt GI bleeding, and efforts should aim at performing it in hospitalized patients. Device-assisted enteroscopy has the benefit, when available, of therapeutic ability and should be performed in the appropriate setting.

	CONCLUSIONS

INTRODUCTION

Acute pancreatitis is a complex disease with a highly variable clinical course. It is responsible for more than 200,000 hospital admissions each year in the United States,¹ and it has an annual incidence of 10 to 80 cases in 100,000 in the developed world.²⁻⁵ Incidence rates have been increasing.⁶ For reasons that are unknown, there is seasonal variation in rates of the disease, the incidence being maximal in the spring and fall.⁷ The crude mortality rate for patients who are hospitalized with acute pancreatitis is less than 2%,⁸ and the majority of patients with acute pancreatitis experience a benign and self-limited disease, resulting in a hospital stay of only several days and no significant lasting sequelae. In a small percentage of patients, however, acute pancreatitis is sufficiently severe to lead to admission to an intensive care or high dependency unit, and a complicated clinical course with a mortality risk that may exceed 20%.^{1,9} These latter patients can present the intensivist with formidable challenges during the course of their illness, but if they recover, as most do, they can return to their premorbid state of health with no significant diminution in quality of life.

The prognosis for patients with severe acute pancreatitis has improved considerably since Ranson proposed his widely used severity criteria. In the mid-1970s, the mortality for patients with severe pancreatitis approached 100%¹⁰; today the risk is less than one quarter of that figure.^{11,12} This improved outcome can be ascribed in part to general improvements in the care of critically ill patients and, more important, to fundamental changes in the approach to the

medical and surgical care of the patient with acute pancreatitis that, in turn, reflect an evolving understanding of the pathophysiology of the disease.

DEFINITIONS AND TERMINOLOGY

Pancreatitis is an acute inflammatory disorder that arises as a consequence of the activation of pancreatic digestive enzymes within the parenchyma of the gland and the surrounding tissues of the peritoneal cavity and retroperitoneum. Its evolution and complications are variable and give rise to terminology that is both confusing and imprecise. The most widely used classification system is that known as the Atlanta classification from 1992¹³ (Table 77.1). Its reproducibility, however, is poor,¹⁴ and it is easier to conceptualize the disease as a spectrum of overlapping abnormalities resulting from the leakage of activated pancreatic enzymes, the host response to local tissue injury, and the superimposed complication of infection of what is initially a sterile process (Fig. 77.1).

In the mildest form of the disease, leakage of activated enzymes is minimal, and the most prominent manifestation is pancreatic edema secondary to a local inflammatory process. In more severe cases, pancreatic ductal disruption results in leakage of pancreatic enzymes into adjacent tissues. If the leakage occurs anteriorly into the peritoneal cavity, fluid collections will be evident. The local peritoneal inflammatory response triggers coagulation and fibrin deposition, walling the collection off and creating a pseudocyst, so called because it is a fluid collection that lacks an

Table 77.1 The Atlanta Classification System for Acute Pancreatitis

Term	Definition
Acute pancreatitis	Acute inflammation of the pancreas with variable involvement of peripancreatic and remote tissues
Mild acute pancreatitis	Edema of pancreas; benign clinical course with minimal organ dysfunction and full recovery
Severe acute pancreatitis	Evidence of pancreatic necrosis; complications of infection, pseudocyst; clinical course characterized by organ failure
Acute fluid collection	Pancreatic or peripancreatic fluid, evident early in course of disease, and lacking wall
Pancreatic pseudocyst	Contained collection of pancreatic juice within a capsule of fibrous tissue and arising following an episode of acute pancreatitis
Pancreatic necrosis	Diffuse or focal loss of viability of pancreatic parenchyma or peripancreatic fat, evident as nonenhancing tissue on a contrast-enhanced CT scan
Pancreatic abscess	Localized collection of pus within pancreas or peripancreatic region and containing little or no necrotic material

Adapted from Bradley EL: A clinically based classification system for acute pancreatitis. Arch Surg 1993;128:586-590.

Figure 77.1 Disruption of the pancreatic ductal system results in leakage of activated digestive enzymes into the peripancreatic tissues. When the predominant direction is anteriorly into the lesser sac, the result is one or more fluid collections that either resolve or coalesce to form a pseudocyst. Leakage posteriorly into the fatty tissues of the retroperitoneum results in fat necrosis.

epithelial lining. Drainage of the pancreatic ascites through the diaphragm can create a pleural effusion; typically this is seen on the left. Marked elevation of the amylase level in the pleural fluid establishes the collection as pancreatic juice, rather than as a reaction to an inflammatory process on the abdominal side of the diaphragm. Alternatively, if leakage is into the fatty tissues of the retroperitoneum, necrosis predominates, although small loculated fluid collections are often present. Often in patients with severe acute pancreatitis, computerized tomography shows evidence of both intraperitoneal and retroperitoneal involvement. The older term, *hemorrhagic pancreatitis*, describes the sequelae of extension of retroperitoneal necrosis into blood vessels of the retroperitoneum. Extraperitoneal tracking of the resulting hematoma gives rise to Grey-Turner's sign when the ecchymosis is evident in the flanks and Cullen's sign when it tracks anteriorly through the falciform ligament to present at the umbilicus.¹⁵

Both necrotic tissue and fluid collections can become secondarily infected with bacteria and fungi from the gastrointestinal tract, the former giving rise to infected pancreatic or peripancreatic necrosis and the latter to an infected pseudocyst or pancreatic abscess—the latter terms being largely interchangeable.

PATHOGENESIS

Acute pancreatitis arises in the pancreas through the leakage of activated pancreatic enzymes into pancreatic and peripancreatic tissues. The characteristic clinical syndrome, however, reflects the activation of a massive systemic inflammatory response to that local tissue injury, mediated through the activation of the inflammasome—a multiprotein intracellular complex that leads to the activation of the key inflammatory cytokine, interleukin-1.¹⁶

Beyond its role as an endocrine organ, the pancreas plays a fundamental role in the digestion of foodstuffs through the production of enzymes that degrade the major constituents of ingested food: protein (proteases), fat (lipases), starch (amylase), and nucleic acids (nucleases). Pancreatic enzymes are synthesized by the acinar cells lining the pancreatic ductal system and released from the cell as inactive zymogens.¹⁷ They pass via the pancreatic duct into the lumen of the duodenum, where they are activated by mucosal enzymes such as enterokinase, and so become capable of degrading their target substrates. Under normal circumstances, activation is vigorously inhibited within the pancreas itself through sequestration of newly synthesized enzymes within zymogen granules, and further through the local action of a specific inhibitor of trypsin activation called SPINK.¹⁸ The importance of normal mechanisms that inhibit trypsin activation is underlined by the observation that genetic mutations in the SPINK gene associated with reduced activity have been implicated in the pathogenesis of hereditary pancreatitis.¹⁹

Acute pancreatitis arises through the activation of pancreatic enzymes within the pancreas itself, possibly through the activity of lysosomal hydrolases in the acinar cell and initiating autodigestion of the pancreas and surrounding tissues.^{20,21} Activation of trypsinogen to trypsin appears to be a critical event during the early pathogenesis of the acute

process,^{22,23} and an increase in intracellular calcium concentrations may contribute to activation of trypsinogen.²⁴ Trypsinogen can also be activated by lysosomal cathepsin B within the acinar cell.²⁵ Pancreatic acinar cells can die by either necrosis or apoptosis. Necrotic death is characterized by cell lysis, with the leakage of intracellular constituents into the surrounding microenvironment and the activation of an acute inflammatory response. Neutrophil recruitment in response to the local tissue injury has been implicated in the amplification of cellular damage in acute pancreatitis.²⁶⁻²⁸ Apoptotic death, in contrast, is noninflammatory. Cells are degraded into membrane-bound vesicles that are taken up by fixed tissue macrophages. Phagocytosis of an apoptotic cell not only prevents the local activation of inflammation but triggers transcriptional programs in the phagocytosing cell that are anti-inflammatory and reparative in nature, with up-regulation of counter-inflammatory cytokines such as interleukin-10 (IL-10).²⁹ The local cellular injury in acute pancreatitis can also be conceptualized as an imbalance between necrotic and apoptotic cell death. Activation of caspases—the intracellular enzymes that mediate apoptosis—attenuate the severity of pancreatitis,³⁰ whereas severe pancreatitis is associated with reduced levels of IL-10.³¹

Activated pancreatic enzymes injure not only cells of the pancreas but also those of surrounding tissues. Fat cells appear to be particularly vulnerable, and the disease tends to be more severe in the obese because of the greater amount of peripancreatic fat necrosis.³² However, the degradative effects of pancreatic enzymes, and the secondary tissue injury resulting from the host response, can injure other structures in the vicinity of the pancreas, in particular, the transverse colon, and major vessels such as the splenic artery and vein.³³ Pancreatitis rapidly evolves from an inflammatory disease of the pancreas to a chemical burn of the retroperitoneum.

The pathogenesis of the clinical syndrome is further complicated by the presence of the gastrointestinal tract immediately adjacent to the pancreas (Fig. 77.2). The head of the pancreas lies within the curve of the duodenum, immediately behind the stomach and above the transverse colon.

Figure 77.2 The pancreas is a retroperitoneal organ, lying posterior to the stomach, within the curve of the duodenum. It lies in immediate proximity to a number of large blood vessels including the splenic artery and vein, the superior mesenteric artery and vein, and the portal vein.

Damage to terminal feeding vessels in the colonic fat caused by activated pancreatic enzymes can result in focal perforation of the colon, with leakage of colonic bacteria into the peritoneal cavity.³⁴ Although the stomach and duodenum are only lightly colonized in health, the local ileus induced by the acute pancreatic inflammation promotes proximal gut overgrowth with enteric bacteria.³⁵ In addition, changes in gut mucosal barrier function arising from local inflammation and the absence of enteral nutrients promote the translocation of luminal bacteria and of bacterial products such as endotoxin into the injured or necrotic peripancreatic tissues.³⁶

Ultimately in the more severe cases, the clinical syndrome evolves as a result of a systemically activated inflammatory response, with the same changes in microvascular blood flow, endothelial permeability, and inflammatory mediator release that characterize bacterial sepsis.³⁷

ETIOLOGY AND RISK FACTORS

Acute pancreatitis has many causes, although 80% of cases in the developed world result from either alcohol or gallstones (Table 77.2). The mechanism of alcohol-induced pancreatitis is unclear. The acinar cell of the pancreas is capable of metabolizing alcohol and also appears to be the primary target of alcohol-mediated pancreatic injury.³⁸ In vitro studies show that alcohol reduces the sensitivity of isolated acini to zymogen activation by cholecystokinin.³⁹ Gallstone pancreatitis appears to be a consequence of a transient acute increase in pancreatic ductal pressures associated with passage of a small gallstone through the sphincter of Oddi in patients with a common channel for the bile

and pancreatic ducts.⁴⁰ True obstruction of the duct is uncommon, and approximately 90% of patients will be found to have gallstones in the stool, implicating the passage of the stone, rather than an obstructing mechanism, in the etiology of the resulting pancreatic inflammation. The list of drugs implicated in the etiology of acute pancreatitis is long⁴¹; some of the more prominent associations are shown in Table 77.2.

Genetic factors have been associated with the development of acute pancreatitis. A polymorphism in the secretory trypsin inhibitor (SPINK1) gene is associated with an increased risk for acute pancreatitis,⁴² as are mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene,⁴³ and PRSS1.⁴⁴ Polymorphisms in the genes for tumor necrosis factor α (TNF α) and heat shock protein 70 have also been linked to an increased risk for acute pancreatitis,⁴⁵ although the association is less clear.

CLINICAL PRESENTATION AND DIAGNOSIS

Acute pancreatitis typically presents as severe acute epigastric pain that radiates to the back, a reflection of the retroperitoneal position of the pancreas. Nausea and vomiting are common associated symptoms. From the perspective of the intensivist, the predominant manifestations of severe acute pancreatitis are those that reflect hemodynamic instability secondary to an activated systemic inflammatory response. These can evolve with alarming rapidity, and the severity of the process is frequently not appreciated until it is quite advanced.

The causes of shock in the patient with acute pancreatitis are multifactorial. Initially, the acute inflammatory process in the retroperitoneum elicits local inflammation, with an outpouring of fluid into the relatively confined space of the retroperitoneum or into the peritoneal cavity itself. Intra-abdominal inflammation evokes secondary ileus within the gastrointestinal tract, and fluid is sequestered here, increasing the relative intravascular volume deficit. Nausea, vomiting, and a reluctance to take fluids by mouth further exacerbate this fluid deficit. As the process evolves, a systemic inflammatory response to the local abdominal process results in diffuse vasodilatation and capillary leak syndrome. In aggregate, the effective loss of intravascular volume can be enormous, and so the initial resuscitation may require large volumes of intravenous fluid. Acute hypocalcemia may also contribute to the clinical picture of cardiovascular compromise. Indeed the classical prognostic criteria articulated by Ranson (Table 77.3) emphasize the importance of acute inflammation (white cell count), and the secondary hemodynamic (fluid sequestration, base excess, blood urea nitrogen [BUN], and hematocrit) and metabolic (glucose, calcium) sequelae in determining the ultimate prognosis.

The diagnosis of pancreatitis is usually straightforward, based on the combination of clinical manifestations and characteristic biochemical findings of elevations in the circulating levels of amylase and lipase, the latter being somewhat more accurate diagnostically.⁴⁶ The diagnosis can be confirmed, and the severity of the disease evaluated by computerized tomography (Fig. 77.3), using the grading system developed by Balthazar⁴⁷ (Table 77.4).

Table 77.3 Ranson's Criteria in Acute Pancreatitis

On Admission	Over First 48 Hours
Age > 55 years	PO ₂ < 60 mm Hg
White cell count > 16,000/ μ L	Estimated fluid sequestration > 6 L
Blood sugar > 11.1 mmol/L (200 mg/dL)	Calcium < 2 mmol/L (8 mg/dL)
LDH > 350 IU/L	Hematocrit fall < 10%
AST > 250 IU/L	BUN rise > 1.8 mmol/L (5 mg/dL)
	Base excess > -4 mEq/L

Figure 77.3 CT findings in severe acute pancreatitis (Balthazar grade E). Note the combination of pancreatic necrosis (black arrow) and fluid and debris (white arrow) and the intimate relationship of the inflamed pancreas to the splenic artery.

An initial assessment of the severity of the disease is useful primarily for deciding the optimal venue for the early management of the patient, as at least some of the delayed morbidity of acute pancreatitis can be reduced through aggressive initial resuscitation and support. Various approaches have been used to quantify disease severity. Ranson identified 11 variables—5 at initial presentation and 6 over the ensuing 48 hours—that correlated in a graded fashion with the ultimate risk of mortality (see Table 77.3). The Glasgow-Imrie criteria are a modification of Ranson's scale and represent an alternate model of severity scoring. In head-to-head studies, Acute Physiology, Age, and Chronic Health Evaluation (APACHE) II—a generic severity of illness scale—performs at least as well as the Ranson or Glasgow-Imrie criteria in predicting hospital survival.⁴⁸ Moreover, even simpler scales appear to provide comparable prognostic information.^{23,49} Various biochemical measures,

including C-reactive protein, procalcitonin, interleukin-6, and trypsinogen activation peptide (TAP), are purported to differentiate mild and severe pancreatitis early during the clinical evolution of the disease⁵⁰⁻⁵²; their clinical utility is unclear. Persistence of clinical manifestations of systemic inflammation beyond 48 hours is also associated with subsequent organ dysfunction and a higher mortality.⁵³ Precision in prognostication is far less important than early recognition of the patient for whom close monitoring and aggressive resuscitation can alter the clinical course, and a low threshold for management in a more controlled and monitored setting is an important factor in reducing the complications of pancreatitis.⁵⁴

EARLY MANAGEMENT OF THE CRITICALLY ILL PATIENT WITH ACUTE PANCREATITIS

INITIAL RESUSCITATION

Intravascular fluid deficits early in the course of pancreatitis can be substantial. Early aggressive fluid resuscitation is the cornerstone of initial successful management.⁵⁵ Volume status should be monitored with a urinary catheter and central venous catheter, and although studies in the specific setting of pancreatitis have not been performed, there is every reason to believe that the principles of goal-directed resuscitation should be followed.⁵⁶ There are no data to support a preference for colloids or crystalloids during resuscitation; the key, however, is to administer sufficient volumes rapidly enough to restore an adequate circulating volume.⁵⁷ Typically this comprises many liters of fluid, and not infrequently, the sickest patients will receive more than 10 to 15 L of fluid resuscitation over the first 24 hours. Such aggressive resuscitation is best carried out within the well-monitored environment of the intensive care unit (ICU).

Although aggressive fluid resuscitation can minimize later complications such as pancreatic necrosis and acute renal failure, in the patient with increased vascular permeability it carries a high risk of complications related to interstitial edema. Frequently patients will require endotracheal intubation and mechanical ventilation. Development of the abdominal compartment syndrome is a relatively common and underdiagnosed complication of resuscitated acute

pancreatitis.⁵⁸ Intra-abdominal pressure can be measured by transducing a urinary catheter in the bladder. Normal pressures approximate the central venous pressure, whereas pressures greater than 20 cm H₂O indicate intra-abdominal hypertension, and pressures greater than 30 cm H₂O indicate a compartment syndrome and carry an increased risk of ischemic injury because of impairment of visceral venous drainage. In severe cases, management requires abdominal decompression by laparotomy. The need for laparotomy in the patient with acute pancreatitis may be avoided by the use of continuous venovenous hemofiltration⁵⁹ or decompressive anterior abdominal fasciotomy.⁶⁰

INFECTION PROPHYLAXIS

Infection is a common complication of acute necrotizing pancreatitis, and its development is associated with an increased risk of morbidity and mortality.⁶¹ For the patient with severe acute pancreatitis, these infections may arise within the injured or necrotic peripancreatic tissues or at distant sites as nosocomial infection in a critically ill patient.

The characteristic microbial flora of peripancreatic infection includes organisms normally resident within the gastrointestinal tract⁶² and organisms that characteristically colonize the proximal gastrointestinal tract of the critically ill patient³⁵ (Box 77.1). Anaerobes may be present but are uncommon, whereas organisms such as *Candida*, *Enterococci*, and coagulase-negative *Staphylococci* are encountered with increasing frequency.^{63,64} This infecting flora reflects the role of the gastrointestinal tract as the reservoir of organisms inducing superinfection during acute pancreatitis.⁶⁵

Infection of necrotic tissue in the retroperitoneum can arise by one of several routes. Bacteremic spread from a distant site, retrograde passage up the pancreatic duct, and direct extension through a defect in the adjacent gastrointestinal tract are all plausible mechanisms. However, the most significant mechanism of infection appears to be as a consequence of the translocation of viable microorganisms

across an anatomically gastrointestinal (GI) tract, from either the colon or the small intestine. Bacterial translocation is readily demonstrable in animal models of acute pancreatitis,^{66,67} and indirect evidence suggests that the phenomenon contributes to infectious complications in human pancreatitis.⁶⁸ Patients with severe pancreatitis, for example, have higher rates of proximal gut colonization with the same enteric organisms that produce infection,⁶⁹ and intestinal colonization invariably precedes the development of invasive infection.⁷⁰ Moreover, suppression of pathologic gut colonization reduces the risk of infection.⁷¹

Host-microbial interactions within the GI tract are complex,^{72,73} and the changes that occur in pancreatitis are much more than a state of generalized leakiness. Colectomy, for example, increases rates of small bowel microbial colonization and bacterial translocation.⁷⁴ Moreover, the anaerobic flora of the gut provides a barrier to intestinal mucosal colonization with pathogenic aerobes and inhibits bacterial translocation.⁷⁵ Thus, anaerobes are uncommonly found in pancreatic infections, and the isolation of an anaerobic organism from an area of infected pancreatic necrosis is highly suggestive of a physical breach of the gastrointestinal tract.

Infection of pancreatic necrosis is a relatively late event, occurring maximally during the second or third week after the onset of the acute disease.⁷⁶ However, circulating bacterial DNA⁷⁷ or endotoxin from gram-negative bacteria⁷⁸ can be detected early during the course of the disease.

The role of antibiotic prophylaxis, however, is controversial. An early meta-analysis of randomized controlled trials of prophylactic antibiotics for patients with acute pancreatitis concluded that prophylaxis can improve survival without significantly altering rates of pancreatic infection.⁷⁹ A consensus conference of critical care organizations, however, has recommended that routine antibiotic prophylaxis should not be used in the absence of more compelling evidence from randomized controlled trials,⁵⁴ and more recent compilations of data from clinical trials fail to show clear evidence of benefit for antibiotic prophylaxis.⁸⁰ A push for conservatism is driven by three principal factors: the low methodological quality of trials supporting antibiotic prophylaxis, concern regarding the adverse ecological consequences of prolonged broad-spectrum antibiotic administration, and the increasing use of an alternate prophylactic strategy, enteral feeding.⁸¹ One of the most influential studies of prophylactic antibiotics in pancreatitis, for example, reported a significant survival improvement associated with antibiotic prophylaxis in a cohort of 60 patients⁸²; in that study, however, antibiotic use had no impact on rates of pancreatic infection, and fully three quarters of patients in the control arm received antibiotics early in the course of their disease. The prevention of pathologic gut colonization through the use of selective digestive tract decontamination has been shown to reduce rates of pancreatic infectious complications⁷¹ and to reduce mortality associated with gram-negative infections.⁸³ Whether antifungal prophylaxis is efficacious is also controversial.^{84,85}

NUTRITIONAL SUPPORT

In contrast to the persistent controversy regarding the utility of antibiotic prophylaxis in severe acute pancreatitis, it is

now generally accepted that patients do better and, in particular, experience less infectious and inflammatory morbidity if they are fed enterally rather than parenterally. Enteral feeding is associated with maintained epithelial barrier function as well as reduced rates of translocation of endotoxin and viable bacteria in experimental animals.^{86,87} A meta-analysis of eight trials recruiting 348 patients found a lower rate of infectious complications (relative risk [RR] 0.39; 95% confidence interval [CI] 0.23 to 0.65), a reduced need for operative intervention (RR 0.44; 95% CI 0.29 to 0.67), a reduced risk of organ failure (RR 0.55; 95% CI 0.37 to 0.81), and a reduced risk of death (RR 0.50; 95% CI 0.28 to 0.91).⁸⁸

Current guidelines recommend the early institution of enteral feeds in patients with severe acute pancreatitis, supplemented, as needed, with parenteral support to meet full nutritional requirements.^{54,89,90} Although the presence of gastric ileus in acute pancreatitis has resulted in a preference for the nasojejunal rather than the nasogastric route of feeding, there is no evidence of the inferiority of nasogastric feeding in more recent clinical trials.^{91,92} Similarly, there is no compelling evidence at present to favor any particular nutritional formulation.

ADJUVANT THERAPY

Despite a substantial body of literature suggesting a benefit for a variety of different adjuvant treatments in preclinical models, there is no evidence for any specific therapy in human disease. A systematic review of the use of cimetidine found no evidence that suppression of gastric acid secretion improved outcome, but rather a trend to a higher risk of complications.⁹³ Pooled data from small studies have suggested that somatostatin or octreotide can improve survival for patients with severe acute pancreatitis,⁹⁴ but data from larger, more robust trials are lacking. Protease inhibitors have also been suggested to reduce mortality in moderate to severe pancreatitis.⁹⁵

Platelet-activating factor (PAF) is a potent pro-inflammatory lipid mediator that has been implicated in the local and remote manifestations of acute pancreatitis.⁹⁶ Inhibition of PAF with either a receptor antagonist⁹⁷ or through the administration of recombinant PAF acetylhydrolase—the enzyme responsible for degrading PAF⁹⁸—results in attenuation of injury in animal models. Unfortunately, despite early promise in phase II clinical trials,^{99,100} a phase III trial failed to show any benefit for adjuvant treatment with the PAF receptor antagonist, lexipafant, in 290 patients with severe acute pancreatitis.¹⁰¹

Other strategies such as inhibition of TNF or blockade of interleukin-1 have shown promise in preclinical models but have not been evaluated in human disease.¹⁰²

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP) IN ACUTE GALLSTONE PANCREATITIS

Gallstone pancreatitis is caused by a gallstone that has migrated from the gallbladder into the common bile duct producing transient obstruction of the pancreatic duct. This pathogenetic mechanism raises the possibility that measures to relieve the obstruction at the level of the sphincter of

Oddi might reduce the severity of the disease. This possibility has been evaluated in at least four clinical trials, the pooled data from which suggest benefit for patients with severe pancreatitis in reducing subsequent complications.¹⁰³ It is unclear whether the benefit extends to all patients or simply to the subset of patients with persistent common bile duct obstruction and concomitant cholangitis.^{104,105}

MANAGEMENT OF THE LATE COMPLICATIONS OF SEVERE ACUTE PANCREATITIS

It is apparent from the foregoing that the early management of the patient with severe acute pancreatitis is focused primarily on adequate resuscitation and organ support. Early lethal postresuscitation complications are uncommon¹⁰⁶ and include intestinal ischemia (typically secondary to a low flow state or mesenteric venous thrombosis following delayed resuscitation)¹⁰⁷ and bleeding secondary to erosion into a major vessel. In the absence of these catastrophic and fortunately rare complications, the subsequent management of the critically ill patient with acute pancreatitis involves optimal intensive care,¹⁰⁸ close monitoring, and patience.

PANCREATIC PSEUDOCYSTS

Serial evaluation by computerized tomography shows that the diffuse fluid collections evident in early pancreatitis coalesce to form discrete cystlike collections contained within an organized capsule of fibrin and termed a *pseudocyst*. Typically these arise in the lesser sac, between the pancreas and the posterior wall of the stomach (Fig. 77.4). Management is expectant in the absence of complications,¹⁰⁹ and rarely is intervention required in the ICU setting. The most common symptom precipitating drainage is persistent pain or symptoms of gastric obstruction. Other important complications include infection and hemorrhage into the cyst.

Figure 77.4 A maturing pancreatic pseudocyst, evident as a well-circumscribed fluid collection in the lesser sac, compressing the residual pancreas (white arrow).

The classic approach to the management of a pancreatic pseudocyst involved waiting until the fibrous capsule of the cyst had matured, then draining the cyst into the back wall of the stomach. Open surgical pseudocyst gastrostomy has largely given way to less invasive approaches, creating a cyst gastrostomy by radiologic image-guided,¹¹⁰ endoscopic,¹¹¹ or laparoscopic approaches.¹¹² A pseudocyst forms because of injury to the main pancreatic duct, or one of its branches, and persists because of obstruction to the flow of pancreatic juice through the duct. If that obstruction persists, then external drainage will result in a persistent pancreaticocutaneous fistula. Thus, regardless of how it is accomplished, drainage into the stomach avoids this complication by replacing the external fistula with an internal fistula that is without clinical importance. Open operation may be required for massive hemorrhage; angiographic embolization of the bleeding vessel is another alternative.¹¹³

INFECTED NECROSIS AND PANCREATIC ABSCESS

One of the more significant advances in the management of severe pancreatitis has been the adoption of a policy of surgical conservatism in managing patients with suspected pancreatic or peripancreatic infection. Case series demonstrate improved survival rates when surgery is delayed,¹¹⁴⁻¹¹⁸ and a single randomized trial showed that delaying surgical intervention for at least 2 weeks in patients with necrotizing pancreatitis improves clinical outcomes.¹¹⁹ This improved outcome can be attributed to a reduced frequency of major bleeding complications associated with the debridement of necrotic, infected retroperitoneal tissue.

Just as serial evaluation reveals localization of pancreatic fluid collections, serial study of areas of pancreatic necrosis shows that they too coalesce with time, becoming more circumscribed and, importantly, developing a wall of granulation tissue between the areas of necrosis and viable surrounding tissues. It is this clear demarcation between viable and nonviable tissue that renders operative intervention safe and obviates the need for repeat operation or open-abdomen approaches. Typically, the process of demarcation takes 3 to 4 weeks or longer to occur; thus, surgical intervention, if contemplated, should be deferred. A strategy of surgical conservatism in the face of a patient with clinical manifestations of sepsis and ongoing organ dysfunction may appear counterintuitive, but it is both well tolerated and safer than the alternative.¹²⁰

There is general consensus that the indication for operative intervention in a patient with severe pancreatitis is infected necrosis; sterile necrosis should be managed conservatively.^{115,121,122} The diagnosis of infection of pancreatic necrosis can be challenging to establish, for clinical manifestations of systemic inflammation are common in the acutely ill patient with pancreatitis, even in the absence of infection, as are nosocomial infections in sites other than the necrotic retroperitoneal tissues. A diagnosis of infection may be suggested by new elevations in levels of procalcitonin^{123,124} or by computed tomography (CT) findings of air in the necrotic tissues (Fig. 77.5). However, definitive diagnosis of infection is best established by CT-guided fine-needle aspiration of the peripancreatic necrotic tissues.¹²⁵

Documentation of infection on a fine-needle aspirate is not an absolute indication for operative intervention.

Figure 77.5 Infected pancreatic necrosis (*white arrow*); the fluid component of the collection was decompressed with a percutaneously placed drain (*black arrow*), allowing delayed laparoscopic debridement.

Antibiotics should be administered as guided by the results of culture and sensitivity and then source control options evaluated. Early in the course of the disease, before the demarcation of necrotic and viable tissues, percutaneous drainage of the fluid component of the collection can temporize until operative intervention is safer (see [Fig. 77.5](#)). Percutaneous drainage alone may be curative,^{126,127} and there is even evolving literature indicating that some patients with infected pancreatic necrosis can be successfully managed nonoperatively.^{128,129}

The surgical management of infected pancreatic necrosis entails the debridement of the necrotic retroperitoneal tissues and drainage of the resulting cavity. Approaches span the surgical spectrum from minimal access techniques¹³⁰⁻¹³² to open abdomen approaches.^{133,134} Improved clinical outcomes have also been seen with the use of less invasive, staged procedures. van Santvoort and colleagues reported a randomized controlled trial of a staged approach to pancreatic necrosectomy, consisting of initial percutaneous drainage of the liquid elements of a pancreatic infection, followed by a minimally invasive necrosectomy, using the drain tract as a route of access.¹² The minimally invasive approach resulted in significantly lower rates of major complications and new-onset organ dysfunction, as well as lower rates of delayed complications including diabetes and incisional hernia. This same group has also reported lower rates of new organ dysfunction and pancreatic fistula when patients were managed by transgastric endoscopic necrosectomy when compared with open necrosectomy.¹³⁵

In general, the optimal approach is the one that entails the least anatomic and physiologic upset to the patient. An open laparotomy can be performed using either a midline or bilateral subcostal incision. With the aid of a recent CT scan to guide the dissection, the infected retroperitoneal necrosis is approached either through the gastrocolic omentum and the lesser sac or through the inferior aspect

of the transverse mesocolon. Dissection is performed largely blindly and bluntly, evacuating necrotic retroperitoneal fat and pus. Soft drains are left in the resulting cavity to provide egress for pancreatic juice, and the abdomen can usually be closed primarily. If there is evidence of significant involvement of the mesocolon or preoperative cultures yield anaerobic organisms, a proximal diverting ileostomy may be added to minimize contamination from the adjacent colon. If the patient is likely to require prolonged ICU care, an operative feeding jejunostomy can facilitate nutritional support.

Laparoscopic techniques have the added advantage of permitting direct visualization of the abscess cavity,^{132,136,137} but they may be challenging if there is extensive or multiloculated areas of necrosis. Infected necrosis can also be approached via the flank, using a nephroscope or laparoscope to aid in visualization of the abscess contents.¹³⁸ Further insights into the role of minimally invasive approaches should emerge from several ongoing clinical trials.^{112,139} The role for open abdomen approaches in the management of infected pancreatic necrosis is diminishing as surgical practice shifts to delayed intervention with more minimally invasive techniques.¹⁴⁰

Peritoneal lavage with the objective of evacuating activated pancreatic enzymes enjoyed a period of popularity¹⁴¹ but is now used less frequently. Some authors recommend continuous postoperative lavage following pancreatic necrosectomy,¹⁴⁰ though the benefits of this approach are unproven.

VASCULAR COMPLICATIONS OF NECROTIZING PANCREATITIS

The vascular complications of acute pancreatitis include both thrombosis and hemorrhage.^{142,143} Thrombosis of the splenic, superior mesenteric, and portal veins develops as a consequence of the pro-thrombotic effects of the adjacent inflamed pancreas and reduced flow prior to full resuscitation. Less commonly, more distant vessels such as the inferior vena cava or renal veins may thrombose. Venous thrombosis may give rise to portal venous gas on computed tomography; in the absence of clinical findings dictating a need for emergent intervention, both the venous thrombosis and the associated CT findings can be managed conservatively.¹⁴⁴ Treatment consists of anticoagulation; intestinal infarction secondary to venous thrombosis in patients with acute pancreatitis carries a prohibitive mortality, even with surgery.

Erosion of the retroperitoneal inflammatory process into a major artery can produce bleeding into either the peritoneal cavity or the gut lumen, in which case it presents as a gastrointestinal hemorrhage. Commonly involved vessels include the splenic artery, the gastroduodenal artery, and the pancreaticoduodenal arcade.¹⁴⁵ Operative exposure is challenging in the face of acute retroperitoneal inflammation, and whenever feasible, bleeding is best managed by angiographic embolization.¹¹³

An algorithm summarizing the key elements in the management of the patient with severe acute pancreatitis is provided in [Figure 77.6](#).

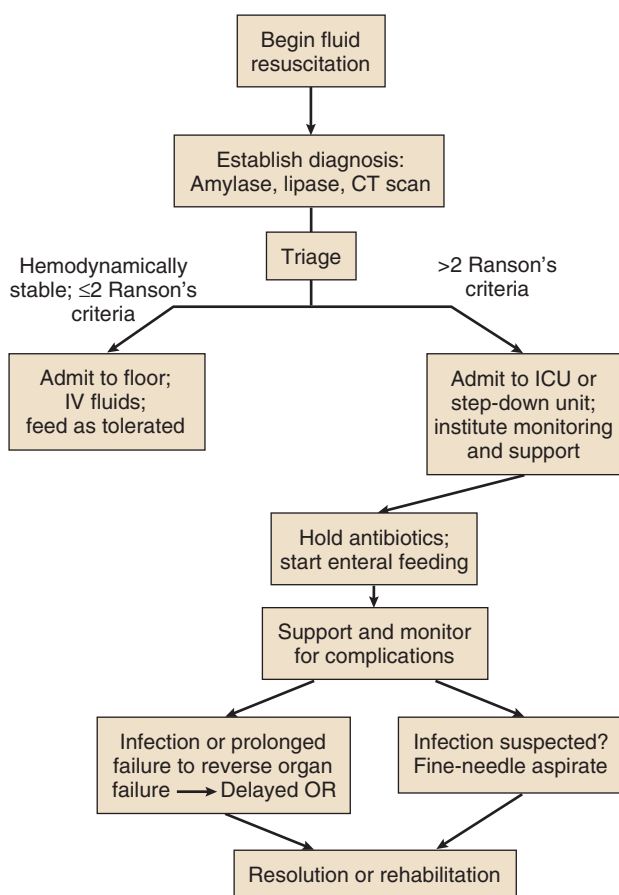

Figure 77.6 Approach to the patient with acute pancreatitis. CT, computed tomography; ICU, intensive care unit; IV, intravenous; OR, operation.

LONG-TERM OUTCOME AND QUALITY OF LIFE

Acute necrotizing pancreatitis can be an enormously challenging process to treat. The ICU and hospital stay is often prolonged, and in addition to operative procedures undertaken during the acute episode, there is often a need for later intervention to close a stoma, repair an incisional hernia, or excise the gallbladder. Yet there is ample evidence that patients who survive their acute illness return to a health-related quality of life that is no different from age-matched controls.¹⁴⁶⁻¹⁴⁹ Abnormalities of both endocrine and exocrine function are commonly evident at follow-up,¹⁵⁰ and approximately one third of survivors of severe necrotizing pancreatitis develop diabetes.¹⁵¹

CONCLUSIONS

Necrotizing pancreatitis is a challenging but enormously satisfying disease to manage. Current management approaches are supportive, with treatment directed at correcting complications of the disease process. Adjunctive treatment strategies that target the pathologic host inflammatory response are not yet available but should emerge.

Although the outcome is heavily dependent on disease severity, with early and aggressive resuscitation, optimal supportive care in an intensive care unit, and judicious and delayed intervention to manage infected necrosis, the overwhelming majority of patients survive and are rehabilitated to an excellent quality of life.

KEY POINTS

- The initial presentation of severe acute pancreatitis can be subtle; early objective quantification of disease severity is important to guide resuscitation and informing decisions regarding patient disposition.
- Aggressive fluid resuscitation is the cornerstone of successful management. Large volumes of intravenous fluids must often be given, and the development of acute respiratory failure with a need for endotracheal intubation and admission to an intensive care unit is neither uncommon nor undesirable.
- The role of prophylactic antibiotics is controversial; in the absence of more compelling evidence of efficacy, their use is discouraged.
- Nutritional support should be instituted early, and by the enteral route, reserving parenteral nutrition for patients who cannot meet their caloric needs by the enteral route.
- There is, at present, no established role for other adjuvant treatments, and support postresuscitation is entirely supportive.
- Serial CT scans can document the severity of the disease and monitor its progression; CT-guided fine-needle aspiration is the diagnostic technique of choice to identify infected necrosis.
- The management of infected necrosis consists of culture-guided systemic antibiotics and delayed surgical intervention. There is an increasing role for minimally invasive techniques of pancreatic debridement and even for nonoperative management of infected necrosis.
- Despite the complexity and morbidity of the acute episode, the long-term health-related quality of life for survivors of acute necrotizing pancreatitis is excellent.

APPROACH TO A CRITICALLY ILL PATIENT WITH HEMORRHAGE OR THROMBOSIS

In the patient with acute hemorrhage or thrombosis, the history taker must be a detective interviewing the patient, family members, and outside health care providers. Useful information includes a personal or family history of a known bleeding disorder; bleeding after previous trauma, surgery, or dental procedures; a personal history of recent bleeding, bruising, or menorrhagia; and a history of liver or kidney disease, malabsorption, or recent chemotherapy. Perhaps the most challenging is obtaining a medication history, particularly as it may relate to covert heparin exposure. The use of anticoagulants, antiplatelet agents, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be determined. Recently started or intermittently used medications (e.g., quinine) that may cause thrombocytopenia should be elicited. In a hypercoagulable patient, a personal or family history of a known thrombophilic defect, thrombosis, recurrent miscarriage, or stillbirth may be useful.

The physical examination can be used to assess active problems, although physical signs of hemorrhage or thrombosis can be subtle. As examples, petechiae or purpura may develop only in dependent areas in a bedridden patient.

The digits and skin should be carefully examined for signs of ischemia or necrosis.

LABORATORY TESTS OF COAGULATION

Although not reflective of the current model of coagulation, the integrity of coagulation is routinely tested by a limited set of in vitro assays (Fig. 78.1). The prothrombin time (PT) reflects the cascade of reactions traditionally called the extrinsic pathway, whereas the activated partial thromboplastin time (aPTT) reflects the intrinsic pathway. They intersect in the common pathway. The thrombin time (TT) measures the rate of conversion of fibrinogen to insoluble fibrin polymer after thrombin is added to plasma. A prolonged TT may be due to an inhibitor of thrombin (e.g., heparin, direct thrombin inhibitor [DTI]), hypofibrinogenemia or dysfibrinogenemia, fibrin degradation products (FDPs), and rarely paraproteins. The only specific coagulation factor that is routinely measured is fibrinogen. These four tests can usually localize abnormalities in the coagulation cascade.

Once a coagulopathy has been identified, the next step is to determine whether it is due to a factor deficiency or a circulating inhibitor. In the inhibitor or mixing study, the

Figure 78.1 Coagulation factors evaluated in routine coagulation assays. aPTT, activated partial thromboplastin time; PT, prothrombin time; TT, thrombin time.

patient's plasma is mixed with an equal volume of normal pooled plasma. Normalization of the PT or aPTT in such a "mixing study" reflects a deficiency of one or more coagulation factors. It also implies that administration of fresh frozen plasma (FFP) should correct the coagulopathy. A further diagnosis requires specific factor assays. If there is partial or no correction in the mixing study, an inhibitor is suspected—most often contaminating heparin or a lupus anticoagulant.

The template bleeding time (BT) assesses *in vivo* platelet function in patients with a normal platelet count. It is used as a screen for disorders of platelet function. The concept of using the BT to predict surgical bleeding is archaic.

DISORDERS OF PLATELETS

THROMBOCYTOPENIA

MECHANISMS AND GENERAL MANAGEMENT

Thrombocytopenia is common in the intensive care unit (ICU). It has been estimated that 23% to 41% of patients in the ICU have a platelet count less than 100,000/ μ L, and 10% to 17% have a count less than 5000/ μ L.¹ Common causes of thrombocytopenia in the ICU are shown in [Box 78.1](#). In complex, acutely ill patients, many of these mechanisms may operate simultaneously. Severe sepsis is the most common cause of thrombocytopenia in the ICU.²

Frequently, thrombocytopenia must be managed without a specific diagnosis. Medications should be reviewed for potential offending agents.^{3,4} Inhibitors of platelet function

Box 78.1 Common Causes of Thrombocytopenia in Critically Ill Patients

Decreased Production

Drugs (e.g., thiazides, linezolid)
Ethanol
Liver disease
Right-sided heart failure

Increased Destruction/Consumption

Bacteremia/sepsis
Drugs
Disseminated intravascular coagulation
Massive bleeding/transfusions
Pulmonary artery catheter
Intra-aortic balloon pump
Ventricular assist device
Idiopathic thrombocytopenic purpura
Burns
Post-transfusion purpura
Thrombotic thrombocytopenic purpura
Antiphospholipid syndrome

Splenic Sequestration

Portal hypertension
Hypothermia

should be avoided with platelet counts below 50,000/ μ L. If there is bleeding or if invasive procedures are anticipated, platelet transfusions should be given, unless contraindicated, to elevate the platelet count above 50,000/ μ L. In life-threatening situations, the goal should be a platelet count higher than 100,000/ μ L. In nonbleeding patients, maintenance of a platelet count above 10,000/ μ L (20,000/ μ L with fever or infection) with prophylactic transfusions is usually adequate.⁵

PSEUDOTHROMBOCYTOPENIA

Pseudothrombocytopenia is a laboratory artifact.⁶ The platelet count is factitiously lowered because of the presence of naturally occurring antibodies that cause platelet agglutination in the presence of ethylenediaminetetraacetic acid (EDTA) at room temperature. The diagnosis is suspected by finding platelet clumps on the peripheral blood smear. Repeating the platelet count with a different anticoagulant such as citrate will generally produce a normal platelet count.

DRUG-INDUCED THROMBOCYTOPENIA

A limited number of drugs have evidence-based data to support a causal role in the development of thrombocytopenia.^{3,4,7,8} Medications commonly used in the ICU can cause thrombocytopenia ([Box 78.2](#)). Drug-induced thrombocytopenia most commonly occurs 7 to 21 days after exposure to the offending agent. Clinical manifestations can range from an asymptomatic decrease in platelets to life-threatening bleeding. The diagnosis is established by (1) finding a temporal relationship between starting the drug

Box 78.2 Drugs Commonly Causing Thrombocytopenia in the Intensive Care Unit

Abciximab
Carbamazepine
Cephalosporins
Clopidogrel
Digoxin
Eptifibatide
Heparins
Hydrochlorothiazide
Linezolid
Quinidine
Quinine
Ranitidine
Tirofiban
Trimethoprim/sulfamethoxazole
Vancomycin

and the fall in the platelet count, (2) having no alternative diagnosis, and (3) having the platelet count recover after removal of the putative offending agent. Unfortunately, this is usually difficult to establish in the typical ICU patient. Treatment is based on removing the putative offending agent and initiating a drug of another class if possible. Though often used, steroids in general have not been shown to hasten the rate of platelet recovery. In severe thrombocytopenia with bleeding such as seen with quinine, intravenous immunoglobulin (IVIG) (1 g/kg/day for 2 days) and platelet transfusion are beneficial.

GLYCOPROTEIN IIB/IIIA INHIBITORS

All platelet glycoprotein (GP) IIB/IIIA inhibitors have been associated with severe thrombocytopenia that can occur within hours of exposure (up to 2 weeks with abciximab).⁷ Heparin-induced thrombocytopenia (HIT) is the main differential diagnosis. Bleeding is very uncommon with HIT because of the strong prothrombotic state. Conversely, with GP IIB/IIIA inhibitor-associated thrombocytopenia, bleeding or hematoma formation may occur, especially at the site of the sheath. A platelet count less than 20,000/ μ L and clinical bleeding are indications for platelet transfusion. The use of IVIG and corticosteroids is not evidence based.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura results from the destruction of IgG-coated platelets in the reticuloendothelial system, primarily the spleen. There is no compensatory increase in thrombopoiesis. Anemia, if present, may be autoimmune (Evans syndrome) or due to bleeding and iron deficiency. Immune thrombocytopenia may be primary (idiopathic [ITP]) or secondary. The differential diagnosis includes pseudothrombocytopenia; immune thrombocytopenia secondary to systemic lupus, human immunodeficiency virus (HIV) infection, or hepatitis C; and drug-induced thrombocytopenia.

Guidelines for the diagnosis and management of ITP have been developed.^{9,10} Indications for therapy in ITP are platelet count less than 20,000 to 30,000/ μ L or clinical bleeding. Corticosteroids (prednisone, 1 mg/kg/day, or

pulse dexamethasone, 40 mg/day for 4 days monthly) are the usual initial therapy for ITP.^{9,10} Individuals with ITP in the ICU usually have severe or life-threatening bleeding. Several modalities of therapy should be used in concert to raise the platelet count in urgent situations (methylprednisolone, 1 g/day for 3 days, and IVIG, 1 g/kg/day for 2 days). Although platelets may be destroyed quickly, platelet transfusions should still be used as initial therapy. The response to platelet transfusion may improve after IVIG is given. Anti-Rh(D) IgG (WinRho), 50 to 75 μ g/kg, has also been used.¹¹ Because the dose of anti-Rh(D) must be reduced in face of anemia, its use may be problematic in a patient with severe bleeding. Anti-Rh(D) IgG is ineffective in Rh-negative patients and after splenectomy. ϵ -Aminocaproic acid (4-5 g IV followed by either 2-4 g IV every 4 hours or 0.5-1.0 g/hour continuous IV infusion [maximum 24 g/24 hours]) may be useful for mucosal bleeding and severe menorrhagia.

POST-TRANSFUSION PURPURA

Post-transfusion purpura (PTP) is a rare condition characterized by acute, severe immune-mediated thrombocytopenia. PTP occurs in human platelet antigen-1 (HPA-1) negative individuals who receive HPA-1 positive platelets (most commonly as a contaminant in packed red blood cells [RBCs]). These individuals have previously been sensitized to HPA-1 through transfusion or pregnancy. Usually 7 to 10 days after reexposure to HPA-1, an anamnestic response occurs, resulting in a precipitous fall in the platelet count. Petechiae and bleeding are common. IVIG and plasma exchange are effective.¹²

ACQUIRED PLATELET DYSFUNCTION

MEDICATION-INDUCED ABNORMALITIES

Aspirin irreversibly acetylates cyclooxygenase (COX), inhibiting platelet function for the life of the platelet (7 to 10 days). The aspirin effect can be overcome with platelet transfusion or the infusion of desmopressin (DDAVP). The effect of NSAIDs is reversible and disappears as the drug is cleared, usually within 24 to 48 hours for ibuprofen. The risk of bleeding from NSAIDs is lowest with ibuprofen and greatest with ketorolac. The thienopyridine clopidogrel tightly binds the platelet ADP P2Y₁₂ receptor. Clopidogrel should be withheld for 5 to 7 days before elective surgery or invasive procedures.¹³ In an emergency, platelet transfusion can be tried, but platelet function may not be fully restored because of circulating active clopidogrel metabolites, which have a half-life of 8 hours and bind to the transfused platelets. Prasugrel is a new thienopyridine whose active metabolites have a 4-hour half-life. COX-2 inhibitors don't affect platelet function.

RENAL FAILURE

The hemorrhagic diathesis of renal failure is the result of metabolic derangements related to uremic toxins.¹⁴ Bleeding may worsen when the hematocrit falls below 30% due to a rheologic phenomenon in which rapidly flowing RBCs gravitate to the center of the streaming blood and force the platelets toward the vessel wall. Uremic bleeding is uncommon in the modern era of dialysis.¹⁵ For clinical bleeding, intravenous DDAVP (0.3 μ g/kg given over 30 minutes) is

often therapeutic.¹⁴ If the hematocrit is less than 30%, the patient should be transfused with packed RBCs.^{14,15} An alternative to DDAVP is cryoprecipitate (10 bags every 12 to 24 hours).¹⁴ Intravenous conjugated estrogen, 0.6 mg/kg/day for 5 days, is also effective.¹⁴ An unexpected “coagulopathy” (prolonged aPTT and TT) may develop as a result of delayed clearance of heparin after dialysis. If available, an anti-factor Xa assay will show the presence of heparin.

THROMBOCYTOSIS

Although not as common as thrombocytopenia, reactive thrombocytosis (splenectomy, surgery, or bleeding) may be seen in the ICU. Reactive thrombocytosis does not have an increased risk of thrombosis. Antiplatelet therapy is not needed even for platelet counts higher than 1,000,000/ μ L.

COMPLEX THROMBOHEMORRHAGIC DISORDERS

HEPARIN-INDUCED THROMBOCYTOPENIA

Although commonly looked for, HIT is an uncommon cause of thrombocytopenia in the ICU.^{2,16} HIT is a paradoxical condition in which modest thrombocytopenia may be associated with devastating heparin-induced thrombocytopenia thrombosis (HITT). Thus, the entire health care team needs to be vigilant for the development of HIT in any patient receiving heparin. HIT has been associated with all types of heparin (unfractionated [UFH] and low-molecular-weight [LMWH]), at any dose, and by any route, including flushes and heparin-coated catheters.^{1,17} The incidence of HIT has been estimated to be less than 1% of patients in the ICU.^{2,16,18} HIT occurs in three time intervals. Classic HIT occurs 5 to 15 days after the initiation of heparin. Rapid-onset HIT develops hours to 1 to 2 days after heparin is started in individuals who have preformed circulating antibodies from a previous exposure to heparin, usually in the last 2 months. Classic and rapid-onset HIT may be manifested as thrombocytopenia with or without thrombosis [HIT(T)]. Delayed-onset HIT occurs an average of 12 days after the discontinuation of heparin and is manifested as isolated thrombosis. The thrombocytopenia of HIT is usually modest with an average platelet count of 50,000 to 60,000/ μ L.¹⁹ Severe thrombocytopenia (<10,000/ μ L) should suggest an alternative diagnosis. HIT may be associated with a normal platelet count if there is a baseline thrombocytosis (e.g., postoperatively). HIT may be manifested as isolated thrombocytopenia or thrombocytopenia with potentially devastating thrombosis. Venous complications include deep venous thrombosis (DVT), pulmonary embolism (PE), cerebral sinus thrombosis, infarctive adrenal hemorrhage, and skin necrosis at the heparin injection site. Arterial complications include iliofemoral artery thrombosis, digital ischemia, myocardial infarction, stroke, and mesenteric artery thrombosis.

HIT is an immune-mediated process in which the heparin–platelet factor 4 complex becomes immunogenic. Antibodies are formed that activate platelets, causing the release of thrombogenic microparticles.^{16,19} The antibodies can also activate monocytes and endothelial cells.

Box 78.3 Clinical Situations to Suspect Heparin-Induced Thrombocytopenia

Current Use of Heparin or Heparin Exposure within 40 Days and at Least One of the Following:

- Platelets <100,000/ μ L
- Platelets <50% of baseline or <50% of the maximum level if reactive thrombocytosis is present
- Platelets less than baseline 5 days after open heart surgery
- New arterial or venous thrombotic event
- Inflammation or necrosis at heparin injection sites
- Acute allergic or anaphylactic reaction to a heparin bolus

Recent Admission to a Hospital, Nursing, or Rehabilitation Facility Plus

- A new venous thromboembolic event
- A new arterial ischemic event

The diagnosis of HIT is clinicopathologic. HIT should be thought of in appropriate clinical situations (Box 78.3). The “4T” score has been used to predict the likelihood (pretest probability) of HIT (Table 78.1).^{16,20} The HEP score, devised by an expert consensus panel, has recently been validated.²¹ Although the decision to initiate therapy should be based on the clinical likelihood of HIT, laboratory testing should be used for the retrospective confirmation of the pretest likelihood of HIT. The complexities of HIT antibody testing are reviewed elsewhere.^{16,22} In general, a strongly positive HIT enzyme-linked immunosorbent assay (ELISA) and strongly positive serotonin release assay (SRA) with a high pretest probability confirm the diagnosis of HIT, whereas a negative ELISA and SRA make the diagnosis of HIT unlikely with a low pretest probability. In other situations, clinical judgment prevails in establishing or excluding a diagnosis of HIT, especially because ELISA and SRA testing from commercial labs has not been validated in clinical studies.^{1,16,22}

Once the diagnosis of HIT is thought to be likely, all heparin should be discontinued. Heparin-coated pulmonary artery catheters should be replaced with noncoated catheters. Catheters for dialysis or apheresis should be locked with 4% citrate or tissue plasminogen activator. The patient’s chart and bedside should be labeled *heparin allergy*. Platelet transfusions should be avoided except for life-threatening bleeding, given the anecdotal observations of acute thrombosis occurring after platelet transfusion. A patient with life- or limb-threatening arterial thrombosis should be evaluated for surgical intervention. Anticoagulation with a DTI (Table 78.2) should be initiated in all patients unless contraindicated. LMWH is contraindicated in HIT caused by UFH. Conversion to warfarin can be considered after a minimum of 5 days of DTI therapy if the platelet count has returned to normal (suggesting that the process has cooled off and the patient is no longer hyperprothrombotic) and no future invasive procedures are planned. Simply discontinuing heparin therapy and not starting a DTI is inappropriate because occult thrombosis may have already developed.²³ Starting or continuing warfarin monotherapy is also contraindicated because of the risk

Table 78.1 Determining Pretest Probability of Heparin-Induced Thrombocytopenia (HIT): The “4 Ts”

Points	Thrombocytopenia	Timing of Onset of Thrombocytopenia (or Other Serious Sequelae)*	Thrombosis or Other Sequelae	Other Causes of Thrombocytopenia
2	>50% decrease and nadir >20,000/ μ L	Day 5-10 or <1 day with recent heparin (past 30 days)	Proven new thrombosis, skin necrosis, or acute systemic reaction to heparin bolus	None evident
1	30-50% decrease or nadir of 10,000-19,000/ μ L	>Day 10 or timing unclear or <1 day with recent heparin (past 31-100 days)	Progressive or recurrent thrombosis, erythematous skin lesions, suspected thrombosis (not proved)	Possible
0	<30% decrease or nadir of <10,000/ μ L	<Day 4 (no recent heparin)	None	Definite

Pretest probability score: 0-3 points = low (<5%), 4-5 points = intermediate (physician judgment), 6-8 points = high (>80%).

*First day of heparin exposure = day 0.

of venous limb gangrene.²⁴ If warfarin has been given at the time HIT is diagnosed, vitamin K should be given to replenish proteins C and S. If invasive procedures are needed (e.g., tracheostomy, pacemaker), it is best to delay them, if medically safe, until the platelet count is normal to minimize the risk of developing thrombosis during the time that DTI

therapy is withheld. Inferior vena cava (IVC) filters should be avoided because of the risk of vena cava thrombosis. Patients with active HIT may need percutaneous coronary intervention (PCI). Argatroban has been approved by the Food and Drug Administration (FDA) for use during PCI in patients with HIT.²⁵ Though not FDA approved,

bivalirudin has been used safely in this situation.²⁶ In a patient who has active HIT or persistent HIT antibodies and who needs open heart surgery, medical management is recommended until the antibody becomes negative. If urgent surgery is needed, bivalirudin is most commonly used.²⁷ For the patient with a past history of HIT who needs open heart surgery and is currently HIT antibody negative, heparin can be used during bypass and a DTI started as soon as it is surgically safe postoperatively.²⁸

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a relatively rare disorder whose hallmarks are thrombocytopenia, microangiopathic hemolytic anemia (MAHA), and neurologic dysfunction. The diagnosis of TTP should be considered in any patient with unexplained thrombocytopenia and MAHA.²⁹ TTP is the clinical manifestation of a heterogeneous group of underlying disorders driven by different pathophysiologic processes. Although most cases of TTP are idiopathic, TTP may be associated with exposure to drugs (e.g., ticlopidine, clopidogrel, quinine, mitomycin C, gemcitabine, cyclosporine), pregnancy, HIV infection, and bone marrow transplantation.³⁰ The morphologic hallmark of TTP is hyaline thrombi in precapillary arterioles composed primarily of platelets. Classic TTP is due to an immune-mediated deficiency of the metalloproteinase ADAMTS13, which cleaves ultralarge multimers of von Willebrand factor (vWF) into smaller forms that are less platelet reactive.³¹ Deficiency of this enzyme allows ultralarge forms of vWF that are normally sequestered in the endothelium to bind platelets and form microthrombi in the circulation. Conversely, ADAMTS13 activity is normal in TTP associated with bone marrow transplantation and the hemolytic-uremic syndrome.^{30,31} Organ dysfunction is due to microvascular thrombosis. Commonly involved organs are the brain, kidneys, heart, and pancreas. It is critical to establish the diagnosis quickly because TTP can be rapidly fatal if not properly treated.

The core laboratory features of TTP are those of MAHA (more than two schistocytes per oil immersion field on a peripheral smear, increased lactate dehydrogenase, and very low haptoglobin). The differential diagnosis includes disseminated intravascular coagulation (DIC), severe vasculitis, eclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, malignant hypertension, sepsis, and malignancy.

Once the diagnosis of TTP is thought to be likely, therapy should be initiated quickly because of the proclivity of the disease to progress rapidly. All patients should initially be treated in the ICU. Platelet transfusions should be avoided except for life-threatening bleeding because of anecdotal reports of acute decompensation after platelet transfusions. A large-bore catheter will need to be placed, even in the face of severe thrombocytopenia, because the mainstay and only evidence-based component of therapy for TTP is plasma exchange.^{32,32a} Most commonly, 1.5 plasma volumes are exchanged daily with FFP. A clue that TTP is the correct diagnosis is the color of the plasma removed from the first plasmapheresis. A red or brown color suggests free hemoglobin from intravascular hemolysis. If plasma

exchange cannot be initiated in a timely manner, infusion of 30 mL/kg of FFP daily can be a temporizing maneuver.³² Corticosteroids (e.g., prednisone, 1 mg/kg/day) are commonly used as well.^{32a} The use of antiplatelet agents, which may increase the risk of bleeding, and vincristine is controversial.³³ In patients who do not respond to initial therapy, rituximab is an attractive second-line therapy.^{30,34}

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome (HUS), the triad of thrombocytopenia, MAHA, and acute kidney injury, is most commonly due to infection with Shiga toxin-producing *Escherichia coli* in children.³⁵ Adult atypical HUS (aHUS) is not Shiga toxin associated. It may be idiopathic or associated with calcineurin inhibitors (cyclosporin, tacrolimus), pregnancy, and HIV. aHUS is associated with low C3 and is a complement deposition disease. Mutations in complement factor H (CFH) are found in a minority of cases. Although not as efficacious as when used for TTP, plasma exchange is used for aHUS. The anti-C5 antibody eculizumab (Soliris) has been FDA approved for the treatment of aHUS.³⁶ Plasma exchange should be initiated while waiting to obtain eculizumab. Supplemental eculizumab dosing is required after each plasma exchange.³⁷ Patients need to receive quadravalent meningococcal vaccine before starting eculizumab.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is always a manifestation of a severe underlying pathologic process (Box 78.4). The final common pathway is the

Box 78.4 Common Causes of Disseminated Intravascular Coagulation

generation of thrombin, which produces microthrombi that can lead to organ dysfunction.³⁸ In the process, natural anticoagulants are consumed and fibrinolysis is activated. Circulating FDPs, along with the consumption of platelets and coagulation factors, lead to a bleeding diathesis. The balance between these competing processes results in the clinical manifestations in any particular individual.

The clinical manifestations of DIC are protean. Microvascular thromboses produce ischemia in many tissues, including the brain (delirium, coma), skin (digital gangrene, purpura fulminans), kidney, lungs (acute respiratory distress syndrome), gastrointestinal tract (mucosal ulceration), and blood (MAHA). The bleeding associated with DIC is due to the combination of depletion of coagulation factors, thrombocytopenia, inhibitory effects of FDPs on coagulation and platelet function, and tissue necrosis with ulceration. Common manifestations are intracerebral hemorrhage, global oozing at lines and venipuncture sites, hematuria, epistaxis, and gingival and gastrointestinal bleeding.

There are no strict, evidence-based laboratory criteria for the diagnosis of DIC.³⁸ The diagnosis is based on identifying an underlying predisposition, the clinical features, and laboratory testing. The most common laboratory features of DIC are thrombocytopenia, elevated FDP or D-dimers, and decreased fibrinogen. The PT and aPTT may or may not be prolonged, depending on the sensitivity of the assay, degree of baseline elevation of coagulation factors as acute-phase reactants, the rate of consumption of coagulation factors, and the amount of FDPs released. An absolute decrease in fibrinogen is very suggestive of DIC. However, fibrinogen activity in the normal range may still be consistent with DIC because fibrinogen is an acute-phase reactant and its level may be inappropriately low for the underlying physiologic state.³⁹ Serial measurement of fibrinogen is often useful. Schistocytes are seen in half the cases. Although the natural anticoagulants antithrombin (AT) (previously called AT-III) and proteins C and S are decreased, and thrombin-antithrombin complexes are increased, their levels usually cannot be measured in real time and are of limited clinical value.

The International Society of Thrombosis and Haemostasis (ISTH) has developed a scoring system for the identification of overt DIC using four commonly available tests (platelets, prothrombin time, FDPs such as D-dimer or soluble fibrin monomer, and fibrinogen) (Table 78.3), which has been prospectively validated.^{40,41} It is important to remember that all the laboratory abnormalities seen in DIC can be caused by other disease processes. Vitamin K deficiency,⁴² a heparin-contaminated blood sample, or a lupus anticoagulant can cause a coagulopathy, whereas elevations in FDPs can be seen with metastatic cancer or can be found after surgery or trauma. Other microangiopathies cause thrombocytopenia and RBC fragmentation. Liver failure can produce a constellation of laboratory abnormalities indistinguishable from those observed in DIC.⁴³

The most important principle in the management of DIC is to treat the underlying cause. If the driving process cannot be controlled, the DIC will progress unabated. Hypothermia and acidosis should be corrected because they interfere with the function of coagulation factors.

Table 78.3 Original ISTH Scoring System for Overt Disseminated Intravascular Coagulation (DIC) and the Modified ISTH Scoring System for Overt DIC in Severe Sepsis

Test	Score
Platelet count (per μL)	
$\geq 100,000$	0
50,000–99,999	1
$< 50,000$	2
D-dimer ($\mu\text{g/mL}$)	
≤ 0.39 (upper limit of normal)	0
0.40–4.0	2
> 4.0	3
Prothrombin time prolongation (s)	
≤ 3	0
> 3 but < 6	1
≥ 6	2
Fibrinogen (mg/dL)	
> 100	0
< 100	1

Original ISTH score: (platelets + D-dimer + PT + fibrinogen) ≥ 5 signifies overt DIC.

Modified ISTH score: (platelets + D-dimer + PT) ≥ 5 signifies overt DIC in severe sepsis.

ISTH, International Society of Thrombosis and Haemostasis; PT, prothrombin time.

Adapted from Taylor FB, Toh CH, Hoots WK, et al: Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. *Thromb Haemost* 2001;86:1327; and Dhainaut J-F, Yan SB, Joyce DE, et al: Treatment effects of drotrecogin alfa (activated) in patients with severe sepsis with or without overt disseminated intravascular coagulation. *J Thromb Haemost* 2003;2:1924.

If the diagnosis is suspected only because of laboratory abnormalities, management should be conservative. Alternative, potentially correctable processes should be kept in mind, such as vitamin K deficiency and drug-induced thrombocytopenia.

If clinically significant bleeding becomes apparent, a patient with overt DIC should receive blood component therapy (cryoprecipitate if fibrinogen is less than 100 mg/dL, FFP, and platelets). A realistic goal is to keep the fibrinogen level 100 to 150 mg/dL, the aPTT close to normal, and the platelet count greater than 50,000/ μL . Heparin is not routinely used for the treatment of DIC. Heparin may be helpful for ischemic manifestations (e.g., digital ischemia, purpura fulminans). A continuous infusion at a rate of 7 U/kg/hour is a reasonable starting dose.

Other treatment modalities have been tried in DIC. The use of AT concentrates showed no significant decrease in mortality rate.⁴⁴ Activated protein C (drotrecogin alfa) used for the treatment of sepsis has been withdrawn from the U.S. market. Because of the intense fibrinolytic activity in DIC, antifibrinolytic agents (ϵ -aminocaproic acid and tranexamic acid) have been tried in an attempt to reduce bleeding. In general, failure rates have been quite high, and

serious thromboses have occurred because the lysis of diffuse microthrombi was suppressed.

DISORDERS OF HEMOSTASIS

It has been estimated that 16% of ICU patients have bleeding caused by a coagulation defect and another 66% have abnormal coagulation test results.

ARTIFACTS

A common cause of an unexplained prolongation of the aPTT is unsuspected heparin in the line from which the blood was drawn. A diagnostic clue is a prolonged TT with a normal fibrinogen. A heparin level (anti-factor Xa assay) will confirm the diagnosis. Although venous access is often an issue in the ICU, blood for coagulation studies should be drawn by venipuncture if possible.

COAGULATION FACTOR ABNORMALITIES

ACQUIRED DEFICIENCIES OF PROCOAGULANTS

Vitamin K Deficiency

Vitamin K is essential for the post-translational modification (γ -carboxylation) of factors II, VII, IX, and X and proteins C and S. The daily requirement of vitamin K is 50 μ g. Normal daily intake of vitamin K is 200 μ g from the diet and 200 μ g from intestinal flora. Thus, vitamin K deficiency occurs commonly in the ICU in the patient who is not being fed and who is receiving antibiotics that alter the gut flora. Vitamin K stores last approximately 1 week.

Because factor VII has the shortest half-life (approximately 4 hours), early vitamin K deficiency is manifested by an isolated prolongation of the PT. As factors II, IX, and X become depleted, the aPTT will become prolonged. Vitamin K deficiency is common in critically ill patients and may result in serious bleeding.⁴² Treatment of vitamin K deficiency depends on the clinical situation. In a nonbleeding patient, vitamin K should be given enterally if the gut is working. Subcutaneous vitamin K should be avoided if the gut is working because of its erratic absorption, especially in face of impaired tissue perfusion and because anaphylactic reactions have been reported with subcutaneous vitamin K.⁴⁵ In a bleeding patient, FFP will correct the coagulopathy most quickly. In critically ill patients with an urgent need for vitamin K replacement, phytonadione may be administered intravenously if the benefits are thought to outweigh the risk of anaphylaxis. Vitamin K should be given no faster than 1 mg/minute with cardiorespiratory monitoring because anaphylactic reactions can occur even at this slow infusion rate.⁴⁵ One milligram of vitamin K twice a week can prevent vitamin K deficiency.

Liver Disease

The perturbation of hemostasis in liver disease is complex. All hemostatic factors except for vWF and plasminogen activator inhibitor-1 are synthesized in the liver. Loss of the ability to synthesize factor VII is disproportionately greater in patients with liver disease than in those receiving warfarin. Thus, the bleeding risk of a prolonged international

normalized ratio (INR) from liver disease is not as great as the same INR with warfarin therapy.⁴⁶ As outlined later, changes in factor VIII/vWF, and decreased synthesis of natural anticoagulants and fibrinolytic proteins, may help keep the patient with liver disease in hemostatic balance,⁴³ making the autoanticoagulation of liver disease promulgated among house staff a myth.

Although hepatic dysfunction is most commonly associated with bleeding, the risk of thrombosis has been underappreciated.⁴³ Synthesis of hemostatic proteins becomes impaired when the albumin falls below 2.5 g/dL. Similar to vitamin K deficiency, the earliest abnormality is a reduction in factor VII. In more severe liver disease, the other coagulation factors become deficient. Factor V and fibrinogen do not usually decrease significantly until the liver failure is severe. In contrast, the activities of factor VIII and vWF are normal or elevated. AT, proteins C and S, and plasminogen are decreased. Hepatic clearance of activated procoagulants and FDP is reduced. Thrombocytopenia may develop due to decreased thrombopoietin production or splenic sequestration. Advanced liver disease may also be complicated by vitamin K deficiency from malnutrition and decreased vitamin K absorption due to cholestasis.

A variety of approaches have been used to treat the coagulopathy of liver disease. If the patient is not bleeding, a trial of vitamin K can be given for 3 days to see if the coagulopathy corrects. Because all patients with liver disease have some degree of biliary obstruction and fat malabsorption, the subcutaneous route is preferred over oral administration. Although the risk of anaphylaxis with intravenous vitamin K is low, it is not generally recommended empirically in a patient with liver disease because of the low likelihood that vitamin K will completely correct the coagulopathy.⁴⁵ If bleeding is a problem, FFP should be administered. Because the relationship between the levels of coagulation factors and the PT/PTT is nonlinear, the greater the prolongation of the PT and PTT, the greater the chance of correction with FFP. However, it is difficult to normalize the PT.⁴⁷ On average, a unit of FFP increases all coagulation factors by 6% to 7%. A typical patient with the coagulopathy of liver disease may have approximately 10% to 15% of the normal level of coagulation factors. If a factor level of 50% of normal is needed for hemostasis, 6 units of FFP would be expected to correct the bleeding diathesis. The PT and PTT may still be prolonged, however, depending upon the sensitivities of PT and PTT assays. The PT (and aPTT) should be checked immediately after the FFP is administered. Given the short half-life of factor VII, waiting until the next morning's routine blood draw will produce a prolongation of at least the PT and give the impression that the coagulopathy is uncorrectable.

Massive Transfusion

Massive volume replacement (>1 blood volume in less than 24 hours) may not give the liver sufficient time to replace coagulation factors. In a hemodynamically stable patient, coagulation studies should be followed serially and FFP infused when a coagulopathy develops. Conversely, exsanguinating patients should be managed with balanced transfusion of RBC:FFP:platelets in a ratio of 1:1:1 (either 1 unit of single donor or 6 units of random donor platelets).⁴⁸

ACQUIRED CIRCULATING INHIBITORS

FACTOR VIII INHIBITORS

The clinical manifestations of factor VIII inhibitors can range from an unexplained prolongation of the aPTT to severe bleeding. The aPTT is markedly prolonged with a normal BT, PT, TT, and fibrinogen. The mixing study does not correct. Further evaluation includes factor VIII, IX, XI, and XII activities and a lupus anticoagulant panel; hematomas should not be drained except in severe circumstances (e.g., compartment syndrome) because of the risk for bleeding, even with replacement therapy. Treatment options depend on the severity of the inhibitor. A low-titer inhibitor (<5 Bethesda units [BU]) may be treated with factor VIII infusion (200 U/kg every 8 to 12 hours). For a high-titer antibody (>5 BU), the treatment options are recombinant human factor VIIa (rH-VIIa; NovoSeven) and virally inactivated concentrates containing activated coagulation factors (FEIBA [factor eight inhibitor bypass activity]). The dose of rH-VIIa is 90 µg/kg, which can be repeated every 2 hours until the bleeding stops. rH-VIIa carries a risk of thrombotic and ischemic events even in individuals with severe coagulopathy.⁴⁹ Coagulation studies are not used to adjust the dose. The PT always falls below the lower end of normal. The FEIBA dose is 50 to 100 U/kg, which is repeated every 6 to 12 hours (maximum daily dose 200 U/kg/day due to thrombotic risk). A total of 500 units of heparin can be added to each bag to prevent infusion phlebitis. The clinical response to FEIBA is monitored.

FACTOR V INHIBITOR

Topical thrombin (a.k.a. fibrin glue) is ubiquitously used in the operating room. Bovine thrombin is contaminated with factor V. Approximately 7 to 10 days after the use of fibrin glue, the PT and aPTT may prolong as a result of the development of antibodies against bovine factor V and rarely factor II. Bleeding is uncommon because platelet factor V is protected from the antibody.

INHERITED DEFICIENCIES OF PROCOAGULANTS

Management of critically ill patients with inherited coagulopathies requires specialized expertise. A hematologist or coagulationist should be consulted. Laboratory measurement of coagulation factor activity should be available on site.

VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is the most common inherited coagulopathy. Synthesized in the vascular endothelium and megakaryocytes, vWF is the ligand that binds to the platelet GP Ib/IX/V complex and promotes platelet adhesion *in vivo*. vWF is a complex multimeric protein, with the largest molecular weight forms having the greatest platelet-binding capacity. Factor VIII procoagulant, which is synthesized by the liver, circulates bound to vWF.

vWD is inherited in an autosomal dominant manner with partial penetrance. The clinical features, diagnosis, and subclassification of vWD are reviewed elsewhere.⁵⁰

Patients with vWD in the ICU most commonly have had major surgery, closed head trauma, major trauma, or life-threatening hemorrhage. The goal of therapy is to increase

vWF activity and factor VIII activity to 100% of normal and to maintain them above 50%. Two virally inactivated factor VIII concentrates available in the United States (Humate-P and Alphanate) are rich enough in vWF to be of clinical use for treating vWD. The other brands of factor VIII concentrate do not contain enough vWF to be of clinical value. rH-VIII, used in hemophilia A, is of no benefit in vWD. The dose is 40 to 50 U/kg of vWF followed by 20 to 25 U/kg every 12 hours. Peak and trough levels of factor VIII (and vWF activity if available) should be obtained to help guide therapy. Doses should be rounded to the size of the nearest vial, if possible, so that these expensive factors are not wasted. In an emergency situation in a smaller facility that does not stock hemostatic factors on site, cryoprecipitate can be used at a dose of two bags per 5 kg followed by one bag per 5 kg every 12 hours until the patient can be transferred to a referral center. In mild cases of type I vWD, DDAVP may be adequate for promoting hemostasis. Repeat doses may be given every 12 hours, although tachyphylaxis will likely develop due to exhaustion of vWF stores in the Weibel-Palade bodies of the endothelium. Patients should be monitored for hyponatremia, especially if large volumes of fluid are given.

FACTOR VIII DEFICIENCY

Factor VIII deficiency (hemophilia A) is an X-linked recessive disorder that occurs in approximately 1 in 10,000 white males. Bleeding characteristically occurs in the joints, soft tissues, and gastrointestinal tract. Although the platelet count should be normal, individuals with hemophilia A complicated by hepatitis C or HIV infection (primarily from exposure to contaminated blood products prior to the era of viral inactivation) may have a concomitant immune thrombocytopenia.

For major surgery, closed-head trauma, major trauma, or life-threatening hemorrhage, the factor VIII level should be raised to 100% and then maintained continuously above 50% for the first 5 to 7 days and above 40% for an additional 5 to 7 days. rH-VIII is the treatment of choice because it has no risk of viral infection. One unit of factor VIII per kilogram should raise the plasma factor VIII activity by 2%. Thus, the initial dose is 50 U/kg followed by 25 U/kg every 8 hours. Peak and trough factor VIII levels should be obtained after the first dose and at least daily. In an emergency situation if rH-VIII is not available, virally inactivated factor VIII would be the treatment of choice. The dosing schema is similar to that of rH-VIII. In an emergency situation in a smaller facility that does not stock hemostatic factors on site, cryoprecipitate can be given every 8 hours until the patient can be transferred. Similar to vWD, DDAVP can be given for mild or moderate factor VIII deficiency in known DDAVP responders. As the hemophilia population ages, coronary artery disease (CAD) is becoming an increasing problem. Individuals with hemophilia A should be supported through indicated cardiac procedures and surgery.⁵¹

FACTOR IX DEFICIENCY

Except for the rate of spontaneous mutations, the clinical picture of factor IX deficiency (hemophilia B) is indistinguishable from that of hemophilia A. The laboratory features are similar except factor IX activity is decreased and

factor VIII activity is normal. The treatment of choice is rH-IX. Because of differences in the volume of distribution in comparison to rH-VIII, the initial loading dose of rH-IX is 100 U/kg followed by half the dose every 12 hours. At least 30% of individuals require a higher dose. Thus, it is not unreasonable to start with a dose of 125 to 150 U/kg, especially in a patient whom you do not want to underdose. Peak and trough levels should be monitored. If rH-IX is not available in an emergency situation, virally inactivated prothrombin complex concentrate (PCC) can be used. The initial dose is factor IX 100 U/kg followed by 50 U/kg every 12 hours. DDAVP and cryoprecipitate are not effective.

FACTOR XI DEFICIENCY

Factor XI deficiency is an autosomal recessive disorder most commonly seen in Ashkenazi Jews. The bleeding history is variable, ranging from menorrhagia to bleeding with delivery or surgery. Therapy depends on the clinical situation.⁵² For severe deficiency, FFP (10 to 20 mL/kg followed by 3 to 6 mL/kg every 6 hours) is used. The goal is factor XI activity greater than 40% to 45%. Individuals with factor XI deficiency may be seen in the ICU because factor XI deficiency is not protective against coronary artery disease. These individuals may require emergency cardiac catheterization and coronary intervention.⁵³ Clopidogrel has been given safely after coronary stenting.⁵⁴

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) is common in critically ill patients. Twenty-nine percent of medical ICU patients have been found to have asymptomatic lower extremity DVT, although 5.8% and 4.2% have symptomatic DVT and PE, respectively.⁵⁵ Most patients admitted to the ICU have multiple risk factors including recent surgery, trauma, sepsis, malignancy, immobilization, stroke, advanced age, heart or respiratory failure, previous VTE, and indwelling catheters.⁵⁵⁻⁵⁷

DEEP VENOUS THROMBOSIS PROPHYLAXIS

All patients admitted to the ICU should be evaluated for their risk for DVT. The perceived risk of thrombosis and bleeding needs to be assessed in each ICU patient.⁵⁵ In medical patients, options are LMWH and UFH.⁵⁵ In medical patients with a high bleeding risk, mechanical prophylaxis (graded compression stockings and intermittent pneumatic compression devices) is recommended.⁵⁵ Beyond the size limitations of this chapter, specific recommendations for DVT prophylaxis are available for trauma, abdominal/pelvic, thoracic, cardiac, and neurologic surgery.⁵⁸

THERAPY FOR VENOUS THROMBOEMBOLISM

In the noncritical care setting, VTE is routinely treated with at least 5 days of UFH, LMWH, or fondaparinux (see Table 78.2), followed by warfarin.⁵⁹ In the ICU, intravenous UFH is the safest mode of anticoagulation given its rapid reversibility for procedures or bleeding. LMWH has the

disadvantages of a longer half-life and being only partially reversed with protamine. As discussed in the section on anticoagulation, fondaparinux should not be used routinely in the ICU. ICU patients should not be transitioned to warfarin given their risk of bleeding and frequent need for invasive procedures. Warfarin is hard to regulate due to frequent drug interactions (especially with antibiotics) and erratic oral intake. Warfarin may stick to feeding tubes.⁶⁰ Warfarin is absorbed in the upper small bowel and may not be absorbed if given via J-tube.⁶¹

INFERIOR VENA CAVA FILTER

Approximately 80% of PE occur as a result of the lower extremity DVT. IVC filter placement is indicated in two situations: (1) acute DVT and a contraindication to anticoagulation (e.g., recent intracranial hemorrhage or stroke, recent neurologic or ophthalmologic surgery, active gastrointestinal hemorrhage, cerebral metastasis with a high risk of bleeding [e.g., melanoma, renal cell, seminoma]⁶²), and (2) recurrent PE despite therapeutic anticoagulation. Filters may have some benefit in face of PE causing hypotension.⁵⁹ IVC filters are not indicated for PE without DVT. IVC filters do not eliminate all risk of PE and do not decrease mortality rates.⁵⁹ There is an approximate 10% risk of thrombosis at the filter insertion site.⁵⁹

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

Catastrophic antiphospholipid syndrome is an uncommon disorder manifested as multiple organ dysfunction secondary to microvascular thrombi. The diagnosis should be considered in patients with an acute onset of more than three of the following: respiratory failure, stroke or other neurologic impairment, abnormal liver function, renal impairment, skin infarction, and thrombocytopenia. Laboratory testing should show evidence of antiphospholipid antibodies. Though not evidence based, empiric therapy has centered around the combined use of high-dose corticosteroids, anticoagulation, and plasma exchange or IVIG.

ANTICOAGULANTS

A variety of parenteral and oral anticoagulants acting through different mechanisms are commercially available with many more in development. Commonly used dosing schema are shown in Table 78.2.

HEPARIN, HEPARIN DERIVATIVES, AND HEPARINOID

HEPARIN

Heparin is a glycosaminoglycan that anticoagulates blood by augmenting the activity of AT.⁶³ Complexes of heparin and AT inhibit thrombin, factor Xa, and other procoagulant proteases. The first five sugars of heparin bind to AT. The

additional sugars determine the protein binding properties and pharmacokinetics of UFH and LMWH.⁶³

UNFRACTIONATED HEPARIN

Binding of heparin to AT varies markedly between individuals, making monitoring a requirement. The anti-factor IIa property of heparin is measured by the aPTT. Because the anti-IIa and anti-Xa properties of UFH are equal, UFH is usually monitored by the aPTT.

The goal of therapeutic heparin is to maintain the aPTT in a range that corresponds to a heparin level of 0.3 to 0.7 U/mL.⁶³ Given the marked variability in aPTT response to heparin because of differences in reagents and laboratory equipment, this range needs to be determined in each laboratory. Because some hospitals do not have a heparin protocol, an adaptation of the Raschke nomogram is shown in Table 78.4.^{63,64} An aPTT ratio of 1.5 to 2.5 times the control value correlates very poorly with the anti-Xa heparin assay and should not be used. The dose of heparin is weight based. No adjustments are needed for obesity, hepatic dysfunction, or renal impairment. The hemoglobin and platelet count should be monitored daily as surveillance for occult bleeding and HIT. Overanticoagulation with heparin can usually be managed by simply interrupting the infusion. With serious bleeding, heparin can be reversed immediately with intravenous protamine sulfate.⁶³ One milligram of protamine will neutralize 100 units of heparin. If bleeding occurs during the constant infusion, the amount of heparin given during the previous 2 hours should be used for the calculation. Thus, a patient bleeding after a 5000-unit heparin bolus will need 50 mg of protamine, whereas a patient receiving a 1250 U/hour infusion will need only 25 mg of protamine. Protamine should be given slowly over 1 to 3 minutes to minimize the risk for hypotension and bradycardia. The risk for anaphylaxis is increased in those who have received protamine zinc insulin or who have had a vasectomy.

LOW-MOLECULAR-WEIGHT HEPARIN

The properties of LMWH vary significantly from those of UFH.⁶³ The anti-Xa:anti-IIa ratio of LMWH is

approximately 4:1. Thus, LMWH does not significantly affect the aPTT. There is little protein binding, allowing for predictable renal excretion. The properties of the available LMWHs (enoxaparin, dalteparin, tinzaparin) are different. Their kinetics and dosing are not interchangeable.⁶³ In a normal-sized adult (50 to 150 kg) with normal renal function, monitoring is not necessary. If monitoring is necessary (weight outside the usual range, impaired renal function, pregnancy), anti-Xa activity is measured 3.5 to 4.0 hours after an enoxaparin dose. The therapeutic range for enoxaparin (1 mg/kg every 12 hours) is 0.5 to 1.0 U/mL. LMWH is only 60% reversible by protamine.⁶³ If bleeding occurs within 8 hours of a LMWH injection, 1 mg of protamine per 100 anti-Xa units should be given. Because of the kinetics of LMWH, a second protamine dose of 0.5 mg per 100 anti-Xa units should be given if the bleeding persists.⁶³

PENTASACCHARIDE

Fondaparinux (Arixtra) is a synthetic analog of the first five sugars of heparin. Due to its small size, it is a pure factor Xa antagonist. Fondaparinux is approved for treatment of DVT and PE and for DVT prophylaxis in orthopedic and abdominal surgery. Although not FDA approved, fondaparinux has been used off-label for the prophylaxis and treatment of HIT(T).¹⁶ As a result of its 18- to 21-hour half-life, its use in the ICU is limited because it is not rapidly cleared in a patient population that needs frequent procedures, that has a high risk of bleeding, and often has renal impairment (contraindicated with creatine clearance [Ccr] < 30 mL/minute). It does not prolong the PT, aPTT, or TT. It can be measured in the anti-Xa assay calibrated for fondaparinux. It is not reversed by protamine. Bleeding due to pentasaccharide should be supported by transfusion. rH-VIIa can be tried.

HEPARINOID

Danaparoid is a mixture of sulfated glycosaminoglycans, distinct from heparin, that produces an anticoagulant effect primarily by enhancing the activity of AT. Danaparoid is primarily used in the setting of HIT. Dosing schema are available for most clinical situations.⁶⁵ If monitoring is necessary, such as during renal failure, anti-Xa activity must be determined. Though no longer available in the United States, danaparoid is available in Canada and Europe.

Table 78.4 Heparin Dosing Nomogram

Anti-Factor Xa (U/mL)	aPTT
Initial dose	80 U/kg bolus, then 18 U/kg/hour
<0.15	80 U/kg bolus, increase by 4 U/kg/hour
0.15-0.29	40 U/kg bolus, increase by 2 U/kg/hour
0.30-0.70	No change
0.71-0.85	Decrease infusion by 2 U/kg/hour
>0.85	Hold 1 hour, decrease infusion by 3 U/kg/hour

aPTT, activated partial thromboplastin time.

Adapted from Raschke RA, Reilly BM, Guidry JR, et al: The weight based heparin dosing nomogram compared with a "standard care" nomogram: A randomized controlled trial. *Ann Intern Med* 1993;119:874.

DIRECT THROMBIN INHIBITORS

As the name implies, DTIs directly bind to and inhibit the function of thrombin. Because of their expense, parenteral DTIs are generally reserved for the treatment of patients with HIT(T) or true heparin allergy. Although none of them have an antidote, rH-VIIa has anecdotally been used off-label to stop life-threatening bleeding. Oral DTIs have recently become available.

Argatroban is an arginine analog with a 40-minute half-life. It is metabolized in the liver, and its half-life increases to around 140 minutes with hepatic dysfunction. Because of its short half-life, an initial bolus is not needed. Although argatroban is monitored by the aPTT, it has a significant effect on the PT.⁶⁶ Argatroban monotherapy will approximately double the INR and can markedly prolong the INR with warfarin cotherapy. As long as the aPTT is therapeutic,

this exaggerated increase in INR does not increase the bleeding risk.

Hirudin is a family of recombinant proteins originally extracted from the salivary glands of leeches.⁶⁷ Lepirudin is used subcutaneously or intravenously. The half-life of intravenous lepirudin is 80 to 180 minutes but extends to days with severe renal failure. Although lepirudin can be removed by hemofiltration, the filters are not approved for use in the United States.⁶⁸ It should not be used in those with sulfite sensitivity. Approximately 40% of individuals exposed to lepirudin will develop antilepirudin antibodies, which will impair drug excretion and which may cause anaphylaxis on reexposure. Lepirudin is no longer produced for the European Union.

Bivalirudin is a reversible synthetic analog of hirudin. Bivalirudin has the advantage of a 25-minute half-life. Although it is cleared primarily by intravascular proteolysis, the dose must be reduced with renal dysfunction. Although not FDA approved, bivalirudin is used off-label in many centers for systemic anticoagulation for HIT(T).⁶⁹ It is also used off-label for bypass surgery in individuals with HIT.²⁷

Dabigatran (Pradaxa) is the first FDA approved oral DTI. It is approved for prevention of stroke and systemic embolization with nonvalvular atrial fibrillation.⁷⁰ It should be used with extreme caution in the elderly, especially because of the risk of bleeding due to overestimation of the Ccr and risk of trauma in the infirm. The dose is 150 mg twice a day (if Ccr > 30 mL/minute). Although not FDA approved, dabigatran has shown efficacy for the treatment of VTE.⁷¹ It binds free and clot bound thrombin, and is primarily cleared via the kidneys with a half-life of 12 to 17 hours.⁷² Drugs that are metabolized via P-glycoprotein may alter metabolism of dabigatran, which is a prodrug. There is no standardized laboratory test to measure the dabigatran level. Thus, in a patient who is having bleeding or thrombotic events while taking dabigatran, there is no test to tell whether the event may be related to over- or underanticoagulation. Given its sensitivity, a normal TT suggests that there is no dabigatran present. How long dabigatran should be discontinued before procedures depends upon the renal function and the bleeding risk of the procedure.⁷² Dabigatran has no antidote. In the bleeding patient, in addition to supportive care and transfusion, the use of activated charcoal (if within 2 hours of ingestion), FEIBA, rH-VIIa, and dialysis have been suggested. Although antifibrinolytics have been shown to decrease bleeding after trauma,⁷³ they should be used with trepidation with FEIBA and rH-VIIa because of the risk of thrombosis.

ORAL FACTOR Xa INHIBITORS⁷⁴

Oral factor Xa inhibitors are undergoing clinical trials for a variety of indications. Because there are no evidence-based data regarding the reversal of oral factor Xa inhibitors in the bleeding patient, they should be used with caution in the ICU.

APIXIBAN

Apixiban (Eliquis), 5 mg twice a day, has been shown to be superior to warfarin for stroke prevention in atrial fibrillation and is under FDA review.⁷⁵ Its elimination is fecal and renal with an 8- to 15-hour half-life. Platelet GP and

strong CYP3A4 inhibitors significantly increase its plasma concentration.

RIVAROXABAN

Rivaroxaban (Xarelto), 20 mg daily, is FDA approved for the prevention of stroke and systemic embolization with nonvalvular atrial fibrillation, and doses of 10 mg daily have been approved for the prevention of VTE with knee and hip replacement surgery.⁷⁶ Although not FDA approved, it has been shown to be efficacious for the treatment of DVT and PE.⁷⁷ It has a 5- to 9-hour half-life (9-13 hours in the elderly) and is metabolized primarily via the cytochrome system. Combined platelet GP and strong CYP3A4 inhibitors may significantly increase the plasma concentration of rivaroxaban. It should be avoided in face of significant hepatic dysfunction, and dose reduction is required for a Ccr less than 50 mL/minute. It should be discontinued at least 24 hours before surgery. Rivaroxaban activity can be measured by the anti-Xa assay used to monitor heparins. Unfortunately, at the time of this writing, standards to calibrate the assay are not available in the United States. Prolongation of the INR by rivaroxaban has been reversed with the use of PCC in healthy volunteers.⁷⁸ There are no data on the efficacy of PCC in bleeding patients. Rivaroxaban is not dialyzable.

Box 78.5 Reversal of Warfarin

International Normalized Ratio (INR) < 4.5, No Bleeding

- Lower dose or
- Omit dose and restart at a lower dose

INR > 4.5 but <10.0, No Significant Bleeding

- Omit 1 or 2 doses and restart at a lower dose, or
- For rapid reversal (e.g., surgery), vitamin K, 3 to 5 mg orally
INR should decrease in 24 hours
Give another 1 to 2 mg if the goal is not reached

INR > 10.0, No Significant Bleeding

- Hold warfarin and
- Give vitamin K, 5 to 10 mg orally
The INR should be significantly reduced in 24 to 48 hours
Give additional vitamin K orally if needed
Resume warfarin when the INR is therapeutic

Any INR, Major Bleeding

- Hold warfarin
- Vitamin K, 5-10 mg by slow intravenous infusion
- Repeat vitamin K every 12 hours as needed
- If urgent correction needed (in order of preference)
Quadravalent prothrombin complex concentrate
Fresh frozen plasma
Recombinant human factor VIIa

Adapted from Hirsch J, Raschke R: Heparin and low molecular weight heparin: The seventh ACCP conference on antithrombotic and thrombolytic therapy. Chest 2004;126:188S; Ageno W, Gallus AS, Wittkowsky A, et al: Oral anticoagulant therapy: Antithrombotic therapy and prevention of thrombosis, 9th ed. ACCP evidence-based clinical practice guidelines. Chest 2012;141:e44S-e88S.

WARFARIN

The vitamin K antagonist warfarin decreases the activities of factors II, VII, IX, and X and proteins C and S. Although prolongation of the PT is often seen within the first 24 to 48 hours after initiation of warfarin due to the decrease in factor VII, 4 to 5 days are required for factors II and X to drop to antithrombotic levels.

The response to warfarin is variable and is affected by many factors common in the ICU, such as poor nutrition (vitamin K deficiency), liver dysfunction, and coadministration of medications that affect warfarin pharmacokinetics. It is not uncommon for patients to become over-anticoagulated with warfarin. An approach to warfarin reversal is shown in [Box 78.5](#).^{79,80}

KEY POINTS

- Hemorrhagic and thrombotic complications in a critically ill patient can usually be anticipated and avoided by careful history taking and physical examination. Routine laboratory tests (platelet count, PT, aPTT, TT, fibrinogen) are helpful in evaluating hemorrhagic disorders but not thrombotic disorders.
- Vitamin K deficiency is a relatively common coagulopathy in critically ill patients, and it is easily treated if recognized.
- von Willebrand disease, the most common inherited coagulopathy, varies highly in clinical severity. Humate-P and Alphanate are the only “factor VIII” concentrates that are therapeutic.
- The bleeding diathesis of uremia can improve with several different treatments, including dialysis, DDAVP, intravenous administration of estrogens, and cryoprecipitate.
- Idiopathic thrombocytopenic purpura (ITP) in adults is usually chronic. If life threatening, several modalities are available for urgent elevation of the platelet count.
- Disseminated intravascular coagulation (DIC) is always a secondary disease process. Treatment must be focused on the underlying cause. If bleeding occurs, blood components should be given. Heparin is generally reserved for clinically evident thrombosis.
- Thrombotic thrombocytopenic purpura (TTP) is a clinical diagnosis associated with multiple inciting events. It is often fatal unless recognized early and treated with plasma exchange.

KEY POINTS (Continued)

- Heparin-induced thrombocytopenia with thrombosis may be life threatening. It should be looked for in any patient with thrombocytopenia who has been exposed to heparin. It can be managed with DTIs.
- Deep venous thrombosis is common in critically ill patients. Prophylactic treatment should be considered for every patient in the ICU. Intravenous UFH is often the safest treatment of established DVT in the critical care setting.
- Novel oral direct thrombin and factor Xa inhibitors are being used with increasing frequency. They have no antidotes for bleeding and there are no evidence-based protocols for their reversal.

Use of Blood Components in the Intensive Care Unit

Michael C. Shen | Janice L. Zimmerman

CHAPTER OUTLINE

BLOOD COMPONENTS AND INDICATIONS FOR TRANSFUSION

Whole Blood and Red Blood Cells
Platelets

Plasma-Derived Components

ADVERSE EFFECTS OF BLOOD COMPONENT TRANSFUSION

Acute Transfusion Reactions
Delayed Nonhemolytic Transfusion Reactions
Transfusion-Associated Circulatory Overload
Transfusion-Related Acute Lung Injury
Transfusion-Associated Graft-Versus-Host Disease
Transfusion-Related Immunomodulation
Transfusion-Transmitted Infectious Diseases
SPECIAL TRANSFUSION SITUATIONS IN THE CRITICAL CARE SETTING
Massive Transfusion

Autoimmune Hemolytic Anemia
Necessary Transfusion of Incompatible Blood
Transfusion in Patients with Disseminated Intravascular Coagulation

Hepatic Failure

ALTERNATIVES TO TRANSFUSION OF BLOOD COMPONENTS

Blood Substitutes
Desmopressin
Antifibrinolytic Agents
Vitamin K
Hematopoietic Growth Factors
Cell Salvage Technology
LEGAL ISSUES IN TRANSFUSION MEDICINE

Transfusion of blood components is a frequent intervention in hospitalized patients, particularly in critically ill patients. An estimated 22,628,000 units of red blood cells (RBCs), platelets, plasma, and cryoprecipitate were transfused in 2008 in the United States.¹ RBC transfusion is often utilized to optimize oxygen-carrying capacity and tissue perfusion that may be due to blood loss, inadequate marrow function, and RBC destruction. Additionally, hemostatic disorders may necessitate the administration of other blood components such as plasma, platelet concentrates, or cryoprecipitate.

Blood components should be considered therapeutic agents with potential benefits as well as adverse effects. Unlike pharmaceutical agents, however, blood components have fewer objective indications for use and no therapeutic index relating dose to safety. Although infectious risks of blood component transfusion have diminished, recognition of risks such as immunomodulation and transfusion-related acute lung injury (TRALI) has increased. Programs of patient blood management are proposed to determine appropriate evidence-based use of blood components and to minimize use of blood products.² Although more quality

evidence has become available to guide clinical decisions in transfusion, many questions remain to be explored through clinical trials, particularly in critically ill patients.

BLOOD COMPONENTS AND INDICATIONS FOR TRANSFUSION

Blood component therapy is used to optimize management of the blood supply. The basic principle of blood component therapy is to use the specific blood product that meets the patient's need. Up to four components (RBCs, plasma, platelets, cryoprecipitate) can be derived from a single whole blood (WB) donation and then distributed to several recipients with differing physiologic needs. Component therapy thus meets the clinical requirements of increased safety, efficacy, and conservation of limited resources. As the variety of available blood product components increases, however, the complexity of transfusion medicine also increases. A WB donation is typically separated into RBCs, a platelet concentrate, and fresh frozen plasma (FFP). The plasma may be further processed into cryoprecipitate and

Table 79.1 Characteristics of Blood Components

Blood Component	Content	Volume (mL)	Plasma (mL)	Shelf Life
Red Cell Products				
Whole blood	RBCs (hct 40–45%), WBCs, plasma, platelets (nonviable)	500–515	~300	21–35 days at 1–6°C (depending on anticoagulant) 24 h if unrefrigerated
Packed RBCs	RBCs (hct 60–80%), WBCs, plasma, platelets (nonviable)	250–300	~25–50 mL	21–42 days at 1–6°C (depending on anticoagulant)
Leukocyte-reduced RBCs (filtered)	RBCs (hct 90%), minimal plasma	200	Minimal	21–42 days at 1–6°C (depending on anticoagulant)
Washed RBC	RBCs (hct 60%), some WBCs	340	0	24 hours
Frozen RBCs	RBCs (hct 90%), minimal WBC and platelets (nonviable)	170–190	0	10 years at –80°C
Platelets				
	Platelets, some WBCs, some RBCs, plasma			Open, 24 hours at 20–24°C with continuous agitation Closed, 5 days at 20–24°C with continuous agitation
Single donor (apheresis)	$\geq 3 \times 10^{11}$ platelets/unit	~300 (200–400)	~250	
Random donor	$\geq 5.5 \times 10^{10}$ platelets/unit	50	50	
Plasma-Derived Products				
Fresh frozen plasma (frozen within 6 to 8 hours of phlebotomy)	Plasma with all coagulation factors and inhibitors, complement, fibrinogen, albumin, globulins	<i>Whole blood donor:</i> 200–250 <i>Apheresis donor:</i> 400–600	200–250 400–600	1 year at –18°C; 24 hours at 1–6°C once thawed
Plasma frozen within 24 hours (separated from whole blood stored at 4–6°C within 24 hours of collection)	Plasma with all coagulation factors and inhibitors but with lower levels of V and VIII; complement, fibrinogen, albumin, globulins	200–250	200–250	1 year at –18°C; 24 hours at 1–6°C once thawed
Cryoprecipitate-reduced plasma (fresh frozen plasma with cold-induced precipitate removed)	Similar to fresh frozen plasma but deficient in XIII, VIII, fibrinogen, and von Willebrand factor	200–225	200–225	1 year at –18°C; 24 hours at 1–6°C once thawed
Cryoprecipitate	Factor VIII (minimum 80 IU), XIII, fibrinogen (minimum 150 mg), von Willebrand factor, plasma, fibronectin	5–20	5–20	1 year at –18°C; 4–6 hours at room temperature once thawed

RBCs, red blood cells; WBCs, white blood cells; hct, hematocrit.

supernatant (cryopoor) plasma. The characteristics of more commonly transfused blood products are described in Table 79.1.

WHOLE BLOOD AND RED BLOOD CELLS

Unseparated venous donor blood with a preservative solution constitutes a WB unit. It contains all blood components, but after less than 24 hours of refrigerated storage, platelet and leukocyte function is lost. With further storage,

levels of the labile coagulation factors V and VIII markedly decrease.³ The growing need for specialized blood components has resulted in processing the majority of blood donations into components, thus limiting the availability of WB. Only 0.03% of total blood transfusions in the United States in 2008 were WB units.¹

RBCs, commonly known as *packed red blood cells* (PRBCs), are the blood component most commonly transfused to increase RBC mass. PRBCs are derived from the centrifugation or sedimentation of WB and removal of most of the

plasma/anticoagulant solution. PRBCs may be further modified to meet the specific needs of patients or blood bank regulations. Leukocyte-reduced PRBCs are the most commonly transfused modified RBC product. Transfusion of blood components containing leukocytes may lead to non-hemolytic febrile transfusion reactions, a greater propensity for platelet alloimmunization, and transmission of pathogens carried by leukocytes, such as cytomegalovirus (CMV). Leukocyte reduction requires filtration of the blood component by a special filter at the time of blood donation and processing or later at the time of transfusion ("bedside filtration"). Leukocyte-reduced RBC units must contain less than 5.0×10^6 leukocytes. Filtration before storage conveys the benefit of removing white blood cells (WBCs) before they can deteriorate and elaborate cytokines and other unwanted substances during storage.⁴ Because of proven and theoretical benefits of leukocyte reduction of blood components (discussed later in the section covering the adverse effects of transfusion), many European countries and Canada require that all PRBCs be leukocyte reduced, a process called *universal leukoreduction* (ULR). Some institutions in the United States have also made that decision, but either method of leukocyte reduction adds significantly to the cost of each transfusion, and the benefits of this measure when applied globally have yet to be quantified.⁵ Almost 70% of transfused PRBCs are leukoreduced in the United States.¹

Washing PRBCs involves recentrifuging in normal saline to remove the plasma/preservative solution from the unit. Washing removes 99% of the plasma proteins and 85% of leukocytes. Washing may take an hour or more, limits subsequent storage time to 24 hours, and causes loss of RBCs (10-20%). Washing is not an effective method of leukoreduction. Washed PRBCs may be indicated for patients with febrile transfusion reactions not prevented by leukoreduction, IgA deficiency with documented antibodies to IgA, and history of a previous anaphylactic reaction to blood transfusion.

PRBCs can also be modified by irradiation to inactivate lymphocytes. Transfusion of irradiated blood is indicated in severely immunocompromised patients at risk of graft-versus-host disease (GVHD), such as transplant recipients, those with aggressively treated malignancies, and those with congenital immunodeficiencies. The transfusion of irradiated PRBCs in the United States is increasing and accounted for 10% of blood transfusions in 2008.¹ Irradiation of RBCs reduces RBC viability and increases release of intracellular potassium.

PRBCs can be frozen in cryoprotective solution and stored for extended periods. Frozen RBCs are generally limited to units of special value, such as those with a rare RBC antigen profile or autologous blood donations that need to be stored for future use. A rare-donor registry of frozen PRBCs exists to assist in providing blood to patients with complex or multiple alloantibodies to RBC antigens. Significant advance planning is necessary to acquire and thaw frozen PRBCs for transfusion, thus limiting their use in acute situations.

RBC components suffer some cell loss during storage. The current technology with preservative solutions attempts to optimize cell quality and quantity by using strict criteria to determine the allowable storage time. Nonetheless, as RBC metabolism decreases progressively, a "storage lesion"

results, with accumulation of a variety of undesirable substances and loss of cellular function.⁶ During storage, a slow rise in the concentration of potassium, lactate, aspartate aminotransferase, lactate dehydrogenase, ammonia, phosphate, and free hemoglobin and a slow decrease in pH and bicarbonate concentration occur. Cytokines and inflammatory mediators such as interleukin 1, interleukin 6, and tumor necrosis factor also accumulate. The pH of freshly stored blood in citrate solution is 7.16, which declines to approximately 6.73 at the end of the unit's shelf life. As potassium leaks from RBCs during storage, levels as high as 25 mEq/L may result. However, each unit transfused supplies at most 7 mEq of potassium, which is usually well tolerated.

During the storage period there is also a progressive decrease in RBC-associated 2,3-diphosphoglycerate (2,3-DPG) and adenosine triphosphate (ATP).⁶ A decrease in 2,3-DPG increases the affinity of hemoglobin for oxygen, which shifts the oxygen dissociation curve to the left and decreases oxygen delivery to tissues. There is little evidence, however, that this transient increase in oxygen affinity has clinical importance. After infusion, 2,3-DPG gradually increases as the transfused RBCs circulate, with 25% recovery in 8 hours and full replacement by 24 hours.⁷ Decreased ATP during storage diminishes the viability of RBCs after transfusion and is one of the chief factors limiting storage time. There is no currently available storage or rejuvenation solution that optimizes these cellular constituents.

The majority of blood transfusions are in the form of PRBCs, the component indicated for normovolemic patients or those for whom intravascular volume constraints are necessary. Resuscitation in patients requiring increased oxygen-carrying capacity and volume is effectively achieved with the use of PRBCs and crystalloid or colloid solutions. Each unit of PRBCs is expected to raise the hemoglobin concentration by 1 g/dL and the hematocrit by 3% in stable, nonbleeding, average-sized adults.

INDICATIONS FOR RED BLOOD CELL TRANSFUSION

Despite a long tradition of transfusion of RBCs in critically ill patients, the precise indications for transfusion remain a source of debate, and transfusion practices may vary widely among clinicians, ICUs, institutions, and geographic regions. Multiple observational studies document transfusion rates in ICU patients that vary from 17% to 53%,⁸⁻¹² and the rate of transfusion increases with longer ICU length of stay.^{8,13} There has been a trend over time for use of a lower transfusion threshold in critically ill patients.^{14,15}

RBCs should be transfused only to enhance tissue oxygen delivery, but the underlying physiology of anemia, the complex adaptations to anemia, and the potential advantages and disadvantages to particular groups of patients are not as well understood. Determining when an anemic patient would truly benefit from increased oxygen-carrying capacity remains an imprecise task. In addition, mounting evidence argues that transfusions may result in donor-recipient interactions deleterious to the critically ill patient, including the disruption of compensatory physiology, the immunomodulation caused by the presence of foreign cells, and the introduction of unintended plasma contents.

Compensatory mechanisms for acute and chronic anemia are complex and work in concert to maintain oxygenation

within the microcirculation.^{16,17} Cardiovascular adjustments leading to increased cardiac output include decreased afterload and increased preload resulting from changes in vascular tone, increased myocardial contractility, and elevated heart rate. Lowered blood viscosity permits improved flow of RBCs within capillaries. Blood flow is redistributed to favor critical organs with higher oxygen extraction such as the heart and brain. Pulmonary mechanisms, though contributing relatively little to short-term oxygenation demands, exert potent effects on related metabolic variables. Finally, the hemoglobin molecule can undergo biochemical and conformational changes to enhance the unloading of oxygen at the capillary level. Increased synthesis of RBC 2,3-DPG in anemia results in a rightward shift of the oxyhemoglobin saturation curve and facilitates the release of oxygen to tissues. A rightward shift of the oxyhemoglobin curve can also occur with a decrease in pH (Bohr effect) but the clinical significance is small.¹⁶ All these mechanisms contribute to an oxygen reserve capacity that exceeds baseline requirements by approximately fourfold. Unfortunately, acute illness and chronic morbidities may limit these compensatory mechanisms in critically ill patients. Animal studies and case reports in patients refusing transfusion indicate that an extremely low hematocrit is tolerated if tissue perfusion is adequate.¹⁷⁻¹⁹

Indirect measurements of tissue oxygen utilization can be derived if patients are monitored invasively with a pulmonary artery catheter, although use of this monitoring tool has significantly decreased in ICUs. Mixed venous oxygen content and arterial oxygen content can be calculated from measured variables. The oxygen extraction ratio (ER), defined as the ratio of oxygen consumption (Vo_2) to total oxygen delivery (Do_2), can be used as a surrogate to determine adequacy of tissue oxygen delivery in the absence of low cardiac output. ER can be calculated by using venous and arterial partial pressures and oxygen saturation values:

$$\text{ER} = (\text{CaO}_2 - \text{CvO}_2) / \text{CaO}_2$$

where the arterial content of oxygen (CaO_2) equals $1.36 \times \text{hemoglobin} \times \text{SaO}_2 + 0.003 \times \text{PaO}_2$. The venous oxygen content (CvO_2) can be calculated by the same formula, replacing the values with mixed venous oxygen saturation (SvO_2) and venous partial pressure of oxygen (PvO_2). Because the contribution of dissolved oxygen in plasma to the oxygen-carrying capacity is negligible, ER can be estimated by: $1 - (\text{SvO}_2 / \text{SaO}_2)$. The total body ER at baseline is about 25%. A falling CvO_2 and an ER increasing to greater than 50% have been proposed as indicators of the need for RBC transfusion, but have never been validated in clinical studies.²⁰

Although RBC transfusion can increase oxygen-carrying capacity and thus oxygen delivery, it may not improve tissue oxygen consumption. Multiple case series evaluating the effects of RBC transfusion in critically ill patients have failed to document increased oxygen consumption or improvement in lactate level.²¹⁻²⁵ Hypotheses to explain this discrepancy include an increase in blood viscosity limiting microvascular flow and impaired tissue and cellular oxygen utilization.

In practice, clinicians usually rely on the hemoglobin to determine when oxygen-carrying capacity is potentially compromised, despite the limitations noted earlier. Prior

transfusion strategies often targeted a hemoglobin goal of greater than 10 g/dL with support of reports that anemia, defined by various criteria, is associated with increased mortality rate in critically ill patients,²⁶ mechanically ventilated COPD patients,²⁷ surgical patients who refuse transfusion,²⁸ and patients undergoing major noncardiac surgery.^{29,30} However, the first large multicenter randomized trial of RBC transfusion strategies in the critically ill showed this liberal transfusion strategy may actually be unnecessary and potentially detrimental.³¹ The Transfusion Requirement in Critical Care (TRICC) trial compared a liberal (target hemoglobin, 10 to 12 g/dL) with a restrictive (target hemoglobin, 7 to 9 g/dL) RBC transfusion policy in 838 euvolemic patients with hemoglobin less than 9 g/dL within 72 hours of ICU admission. The primary outcome measure of 30-day all-cause mortality rate was not statistically different between the restrictive strategy and the liberal strategy ($p = 0.11$). A secondary outcome measure of overall hospital mortality rate was significantly lower in the restrictive strategy group ($p = 0.05$). The restrictive strategy was superior for subgroups of patients younger than 55 years and patients with lower (<20) APACHE (Acute Physiology, Age, and Chronic Health Evaluation) II scores. In addition, liberal transfusion was not associated with shorter ICU or hospital stays or less organ failure; longer mechanical ventilation times and cardiac events were more frequent in the liberal strategy group. A separate analysis of 713 patients in the study who received mechanical ventilation did not find any significant differences between treatment groups for the duration of mechanical ventilation or extubation success.³² Similarly, a subgroup analysis of 357 patients from the TRICC study with cardiovascular disease did not find any differences in mortality rates between the restrictive and liberal strategies.³³

The results of the TRICC study were replicated in a study of transfusion strategy in critically ill pediatric patients.³⁴ A liberal transfusion threshold of 9.5 g/dL was compared with a restrictive transfusion threshold of 7.0 g/dL. The primary outcomes of death and new or progressive multiple organ dysfunction as well as adverse events were similar in both treatment groups, but 54% of patients in the restrictive group did not receive transfusion as compared to only 2% in the liberal group ($p < 0.001$). Subsequent prospective randomized trials have validated the use of a restrictive transfusion strategy in other adult patient populations.³⁵⁻³⁹ Although a small study of liberal (hemoglobin threshold of 10 g/dL) versus restrictive (hemoglobin threshold of 8 g/dL) transfusion in 120 hip fracture surgery patients raised concern for increased cardiovascular complications and mortality rate with a restrictive strategy,⁴⁰ a larger trial in 2016 high-risk patients undergoing surgery for hip fracture found no increase in mortality rate and no difference in functional recovery.³⁵ The Transfusion Requirements After Cardiac Surgery (TRACS) study compared transfusion thresholds of hematocrit less than 30% with hematocrit less than 24% from the start of surgery through the ICU stay.³⁶ There was no difference in the composite outcome of 30-day all-cause mortality rate and severe morbidity between the liberal and restrictive strategies, and fewer blood products were administered in the restrictive group. These results are similar to those in an earlier study in coronary artery bypass surgery patients that evaluated liberal and restrictive transfusion strategies in the postoperative period.⁴¹

The TRACS study and the analysis of patients with cardiovascular disease from the TRICC study suggest that RBC transfusion using a hemoglobin threshold of 7 to 8 g/dL in stable patients at risk for myocardial ischemia is well tolerated. However, these studies do not answer the question of whether patients with acute coronary syndromes (current or recent ischemia) would benefit from a liberal transfusion strategy. Results from retrospective and prospective observational studies of anemia and transfusion in acute coronary syndrome patients have yielded conflicting results.⁴²⁻⁴⁵ A recent prospective, randomized pilot study of 45 patients with acute myocardial infarction (MI) and hematocrit 30% or less compared a transfusion threshold of hematocrit less than 24% with hematocrit less than 30%.⁴⁶ The composite safety end point of in-hospital death, new MI, or new or worsening heart failure occurred in 38% of the liberal strategy patients versus 13% in the conservative strategy patients ($p = 0.046$). These results suggest that even in acute MI moderate anemia may not be as harmful as the risks involved with transfusions. Larger studies in the future should help determine whether a restrictive transfusion strategy should be adopted in patients with acute coronary syndromes.

Prior guidelines for transfusion of RBCs did not specifically address critically ill patients and were primarily based on consensus rather than evidence.⁴⁷⁻⁵¹ Transfusion was usually recommended if hemoglobin was less than 6 or 7 g/dL and not indicated when hemoglobin was greater than 10 g/dL.^{48,52} Guidelines of the American Association of Blood Banks⁴⁶ and the Society of Critical Care Medicine/Eastern Association for Surgery of Trauma⁵³ and a Cochrane review⁵⁴ provide an evaluation of clinical evidence and more specific recommendations that are applicable to the critically ill. A summary of the guideline recommendations is presented in **Box 79.1**. Transfusion of single units of RBCs is recommended except in the setting of acute hemorrhage.⁵³ Implementation of a restrictive transfusion practice as recommended by the guidelines could decrease patient RBC exposure by an estimated 40%.⁴⁶ The threshold for administration of RBCs should also be considered as part of a comprehensive, multidisciplinary patient blood management program to detect and treat anemia, reduce surgical blood loss, and optimize hemostasis.²

PLATELETS

Platelet components are available as random donor units or single donor apheresis units. Because of the limited storage time and the increasing demand for this component, platelets are often subject to supply shortages. A random donor platelet concentrate is obtained by centrifugation from a unit of WB. This type of platelet concentrate contains up to 50% of the leukocytes from the WB unit. The average transfused dose of random donor platelets has been decreasing over time and is now 5 units in the United States.¹ If bags are entered for pooling before transfusion, the platelets must be administered within 4 hours. A single donor apheresis platelet unit contains the equivalent of 4 to 6 units of random donor platelet concentrates. This type of platelet concentrate is considered to be leukoreduced and no additional filtration is needed. Single-donor platelets offer the benefit of reducing the risk of multiple-donor exposure to

Box 79.1 Guideline Recommendations for Transfusion of Red Blood Cells

American Association of Blood Banks (2012)

- Adhere to a restrictive strategy in hospitalized, hemodynamically stable patients (*strong recommendation*)
 - Adult ICU patients: consider transfusion when hemoglobin ≤ 7 g/dL
 - Postoperative surgical patients: consider transfusion when hemoglobin ≤ 8 g/dL or for symptoms (chest pain, heart failure, orthostatic hypotension, tachycardia unresponsive to fluid resuscitation)
- Adhere to a restrictive strategy in hospitalized, hemodynamically stable patients with preexisting cardiovascular disease (*weak recommendation*)
 - Consider transfusion when hemoglobin ≤ 8 g/dL or for symptoms
- No recommendation for a specific transfusion strategy in hospitalized, hemodynamically stable patients with acute coronary syndrome

Society of Critical Care Medicine/Eastern Association for Surgery of Trauma (2009)

- Transfusion is indicated for patients with hemorrhagic shock and may be indicated for patients with acute hemorrhage and hemodynamic instability or inadequate oxygen delivery.
- Transfusion when hemoglobin is < 7 g/dL (*restrictive strategy*) is as effective as transfusion when hemoglobin is < 10 g/dL (*liberal strategy*) in critically ill hemodynamically stable patients.
- Transfusion may be beneficial in patients with acute coronary syndromes with hemoglobin < 8 g/dL on hospital admission.

ICU, intensive care unit.

the recipient, and may also be the only available alternative for recipients who have been alloimmunized by previous platelet transfusions. Apheresis platelets now account for 87% of all platelets transfused in the United States.¹

Platelets are stored at room temperature to avoid loss of function from refrigeration and are constantly agitated to maximize gas exchange. Some loss of viability and platelet numbers occurs during storage, but 5-day-old platelets still effect hemostasis. The plasma contained in platelet concentrates is a good source of stable coagulation factors and contains diminished but still potentially beneficial amounts of factors V and VIII. Platelet components may be modified by leukocyte reduction, irradiation, and washing similar to that for RBCs. Transfusion of ABO-compatible platelets is desirable but not essential. When ABO-mismatched platelets are given, removal of some of the incompatible plasma can be carried out prior to transfusion. Single donor apheresis platelets may be matched to an alloimmunized recipient for human leukocyte antigens (HLA) or platelet antigens. There is no contraindication to the use of Rh-positive platelets in Rh-negative patients. However, if Rh-positive random donor platelets are administered to Rh-negative women

with childbearing potential, Rh immune globulin should be used prophylactically due to the small risk of Rh alloimmunization from RBCs that may be contained in the platelet concentrate. In similar circumstances, Rh immune globulin is not indicated if single donor apheresis platelets are transfused because they contain few RBCs.

Each unit of random donor platelets is expected to increase the platelet count by $10 \times 10^9/L$ in a typical 70-kg adult. A 1-hour posttransfusion platelet count should be obtained to determine the adequacy of response. The following equation, which relates platelet number and body size to the posttransfusion increment, can be used to assess the effectiveness of the transfusion:

Corrected count increment (CCI)

$$= \frac{\text{Observed rise in platelet count} \times \text{Body surface area (m}^2\text{)}}{\text{Number of platelet units transfused}}$$

A CCI of $10 \times 10^9/L$ or higher can be considered a good response, whereas a CCI of $5 \times 10^9/L$ or lower indicates a poor response to transfusion.⁵⁵ The increment in platelet count is higher with single-donor apheresis units, ABO-identical platelets, and platelets stored no longer than 3 days.^{56,57} However, there is no advantage of these platelet characteristics on prevention of clinical bleeding.⁵⁶

INDICATIONS FOR PLATELET TRANSFUSION

Although the prevalence of thrombocytopenia in the critically ill varies with the definition used and clinical setting, thrombocytopenia is associated with platelet transfusions and increased mortality rate in ICU patients.^{58,59} Guidelines for transfusion of platelets are derived from consensus opinion and experience primarily in patients with chemotherapy-induced thrombocytopenia rather than critically ill patients.^{48,60-63} Extrapolation of these guidelines to critically ill patients is problematic because the cause, risks, and consequences of thrombocytopenia may be different. Indications for platelet transfusions include active bleeding due to thrombocytopenia or functional platelet defects (therapeutic transfusion) or prevention of bleeding due to thrombocytopenia (prophylactic transfusion). The majority of platelet transfusions in the ICU are performed for prophylactic indications and often do not result in an increase in platelet count.⁶⁴

Suggested indications for platelet transfusion are summarized in Table 79.2. There is good evidence that medical or surgical patients with active bleeding and platelet counts of $50 \times 10^9/L$ or above will not benefit from transfusion if thrombocytopenia is the only abnormality. Prophylactic platelet transfusions are administered to prevent spontaneous bleeding or bleeding with invasive procedures. The threshold for platelet transfusion prior to invasive procedures is usually recommended as less than $50 \times 10^9/L$, but transfusion decisions should take into account the type of procedure, bleeding risks associated with the procedure, consequences of bleeding, and concomitant factors affecting hemostasis. For critical invasive procedures in which even a small amount of bleeding could lead to loss of vital organ function or death, maintaining the platelet count greater than $50 \times 10^9/L$ is typically preferred. The presence of factors that diminish platelet function, such as certain

Table 79.2 Indications for Platelet Transfusion

Clinical Situation	Platelet Count: $\times 10^9/L$
Therapeutic	
Active bleeding	<50
Prophylactic	
Spontaneous bleeding risk very high	0-10
Spontaneous bleeding risk high with concomitant coagulation abnormality, anticoagulant therapy, sepsis, fever, concurrent antibiotic use, rapidly decreasing count or planned invasive procedure	11-20
Planned invasive procedure	21-50
Consider with platelet dysfunction (uremia, antiplatelet drugs) and planned invasive procedure when other therapies are ineffective	>50

drugs, foreign intravascular devices (e.g., intra-aortic balloon pump or membrane oxygenator), infection, or uremia, alter this requirement upward. Patients at risk for small but strategically important hemorrhage, such as neurosurgical patients, may need to be maintained at platelet counts of 80 to $100 \times 10^9/L$.

The most appropriate platelet count for procedures that may be performed in critically ill patients, such as placement of central venous catheters and arterial catheters, thoracentesis, and paracentesis, has not been defined. A retrospective study suggests that central venous catheters can be placed safely when the platelet count is greater than or equal to $20 \times 10^9/L$.⁶⁵

Patients undergoing cardiac bypass surgery experience a drop in platelet count and often acquire a transient platelet functional defect from damage associated with the bypass apparatus.⁶⁶ Most patients do not experience platelet-associated bleeding, however, and prophylactic transfusion in the absence of bleeding is not warranted. In a patient who continues to bleed postoperatively, more likely causes are a localized, surgically correctable lesion or failure to reverse the effects of heparin. If these conditions are excluded, empiric transfusion of platelets may be justified.

Patients without hemorrhage who have platelet counts of $5 \times 10^9/L$ or lower are at increased risk for significant spontaneous bleeding, and the majority of guidelines propose prophylactic platelet transfusion to prevent hemorrhage at a threshold of $10 \times 10^9/L$ or less. The recommendations are based on experience in patients with hematologic malignancies and chemotherapy-induced underproduction of platelets. The prior practice of transfusion to maintain the platelet count above $20 \times 10^9/L$ derives from data published in 1962, which demonstrated an increase in spontaneous bleeding in leukemic patients at that level.⁶⁷ However, critical evaluation of the data reveals that serious hemorrhage was not greatly increased until counts fell to $5 \times 10^9/L$ or lower and that these patients received aspirin for fever, which might have compromised platelet function and enhanced bleeding.

A prospective study of a more conservative platelet transfusion protocol found that major bleeding episodes occurred on 1.9% of days with counts of less than $10 \times 10^9/L$ and on only 0.07% of days with counts of 10 to $20 \times 10^9/L$.⁶⁸ Additional studies have confirmed the safety of using less than or equal to $10 \times 10^9/L$ as a prophylactic platelet transfusion threshold in patients with hematologic malignancies or stem cell transplants.⁶⁹⁻⁷² The trigger for prophylactic platelet transfusion of less than or equal to $10 \times 10^9/L$, however, applies primarily to a specific population of stable thrombocytopenic patients. Factors such as fever, use of anticoagulant or antiplatelet drugs, and invasive procedures must be considered when generating a treatment plan for individual patients. Patients experiencing rapid drops in platelet count may be at greater risk than those at steady state and thus may benefit from transfusion at higher counts. Prospective studies in critically ill patients have not been reported. Benefits to the patient of more conservative use of platelet transfusion include decreased donor exposure, which lessens the risk of transfusion-transmitted disease; fewer febrile and allergic reactions that may complicate the hospital course; and the potential delay or prevention of alloimmunization to HLA and platelet antigens.⁷³

Patients thrombocytopenic by virtue of immunologic destructive processes such as idiopathic thrombocytopenic purpura (ITP) receive little benefit from platelet transfusions because transfused platelets are rapidly removed from the circulation. In the event of life-threatening hemorrhage or an extensive surgical procedure, transfusion may prove beneficial for its short-term effect but may require higher doses of platelets. Transfusion may be accomplished effectively by pretreatment with high-dose immunoglobulin or high-dose anti-D antiserum.^{74,75} Platelet transfusion is contraindicated in thrombotic thrombocytopenic purpura (TTP),⁷⁶ hemolytic-uremic syndrome, and heparin-induced thrombocytopenia. Cautious administration of platelets may be considered in cases of life-threatening thrombocytopenic bleeding.

The development of refractoriness to platelet transfusions due to alloimmunization is a serious event. Poor response to platelet transfusions due to increased platelet consumption also occurs with splenomegaly, fever, trauma and crush injury, burns, disseminated intravascular coagulation (DIC), concomitant drugs, and transfusion of platelets of substandard quality.⁷⁷ These factors should be identified and corrected if possible. Alloimmunization is characterized by the development of anti-HLA or platelet-specific antibodies, with resultant immune platelet destruction. As many as 70% of patients receiving multiple RBC or platelet transfusions become immunized.⁷³ Leukocyte depletion of transfused components can prevent or delay this phenomenon, but it is important to use leukoreduced components early in the course of transfusion therapy.^{73,78} When patients fail to achieve expected increments after platelet transfusion, provision of ABO-specific platelet concentrates that are less than 48 hours old may improve the response. If no improvement is seen, the patient should be screened for HLA antibodies or be HLA typed and provided with HLA-compatible single-donor platelets. Alternatively, platelet crossmatching with the patient's serum can be carried out. There is no advantage to unmatched single-donor platelets in this situation.

PLASMA-DERIVED COMPONENTS

PLASMA

Standard FFP is prepared by centrifugation of WB or single-donor apheresis and is frozen within 8 hours of blood donation. Standard FFP contains all coagulation factors (including the labile factors V and VIII) and inhibitors, approximately 400 mg fibrinogen, complement, albumin, and globulins. By convention, the coagulation factors are present in concentrations of 1 U/mL. Plasma that is separated and frozen from refrigerated WB more than 8 hours but within 24 hours of phlebotomy is referred to as PF24. PF24 differs from standard FFP by having lower levels (approximately 15% to 25% reduction) of factors V and VIII, but the decrease in labile factor levels is not considered to be clinically significant. The processing technique for PF24 allows for clinical utilization of plasma collected at distant sites and increases the plasma supply. Cryoprecipitate-reduced plasma (also called *cryopoor plasma*) refers to FFP with the cold-induced precipitate removed. Cryopoor plasma will thus be deficient in factors VIII and XIII, fibrinogen, and von Willebrand factor. In the United States, FFP accounted for 54% of plasma transfusions and PF24 accounted for 39%.¹ The most common method of thawing FFP requires about 30 to 45 minutes in a 37°C water bath. Crossmatching to the recipient is not performed, but FFP must be ABO compatible. Standard FFP is as likely to transmit hepatitis, HIV, and most other transfusion-related infections as cellular components. The following types of pathogen-reduced plasma products are available in some countries outside the United States: solvent/detergent-treated plasma, methylene blue-treated plasma, psoralen- and ultraviolet light-treated plasma, and riboflavin- and ultraviolet light-treated plasma.⁷⁹

Indications for Fresh Frozen Plasma

FFP is frequently transfused inappropriately in critically ill patients who are not bleeding or in whom the international normalized ratio (INR) is less than 1.5.^{80,81} Guidelines for transfusion of FFP have been primarily based on expert opinion rather than clinical evidence (Box 79.2).^{60,82,83} A summary of practice recommendations for specific clinical circumstances based on a systematic review is presented in Box 79.3. The review emphasized the lack of high-quality evidence on plasma infusion and the need for well-designed trials to address relevant knowledge gaps.⁸⁴

Box 79.2 Guideline Recommendations for Transfusion of Fresh Frozen Plasma

Acquired deficiency of coagulation factors with abnormal coagulation tests AND
Active bleeding
OR
Planned surgery or invasive procedure
Immediate reversal of warfarin effect with active bleeding or planned procedure
Thrombotic thrombocytopenic purpura
Congenital factor deficiency with no alternative therapy
Rare protein deficiencies (protein C or S)

Box 79.3 Recommendations Regarding Fresh Frozen Plasma (FFP) Transfusion in Specific Conditions*

1. Suggest that FFP be transfused to trauma patients requiring massive transfusion
2. Cannot recommend for or against of FFP transfusion at a plasma-to-RBC ratio of 1:3 or more in trauma patients with massive transfusion.
3. Cannot recommend for or against FFP transfusion in patients undergoing surgery in the absence of massive transfusion.
4. Suggest FFP be transfused in patients with warfarin-related intracranial hemorrhage.
5. Cannot recommend for or against FFP transfusion to reverse warfarin in patients without intracranial hemorrhage.
6. Suggest against FFP transfusion in other groups of patients (in the absence of massive transfusion, surgery, bleeding, or overanticoagulation)

*Based on a systematic review.

Adapted from Roback JD, Caldwell S, Carson J, et al: Evidence-based practice guidelines for plasma transfusion. *Transfusion* 2010;50:1227-1239.

FFP should be administered only to provide coagulation factors or plasma proteins that cannot be obtained from safer sources. FFP is commonly used to treat bleeding patients with acquired deficiency of multiple coagulation factors, as in liver disease, DIC, or dilutional coagulopathy. However, changes in INR after FFP transfusion are usually minimal and not clinically significant when the pretransfusion INR is less than 2.0.^{81,85} FFP may be indicated for the provision of protein C or S in patients who are deficient and suffering acute thrombosis. FFP should be administered as boluses as rapidly as feasible so that the resulting factor levels achieve hemostasis. The use of FFP infusions is not helpful. Variable doses of FFP have been recommended including 2 units initially (probably underdosage) up to 10 to 15 mL/kg. However, some studies suggest that doses as high as 30 mL/kg may be needed to achieve adequate factor levels.⁸⁶ Due to the short half-life of factor VII, FFP should be infused every 6 to 8 hours if bleeding continues. FFP should not be used for volume expansion or as a nutritional source of protein. Anticoagulation induced by heparin, direct thrombin inhibitors (e.g., dabigatran), or direct factor Xa inhibitors (e.g., rivoraxaban) is not reversed by FFP.

Patients do not usually bleed as a result of coagulation factor deficiency when the INR is less than about 2.0, and even then the results are not always predictable.⁸⁷ The partial thromboplastin time (PTT) is also not useful in predicting procedural bleeding risk.⁸⁸ Prophylactic administration of FFP does not improve patient outcome in the setting of cardiac surgery unless there is bleeding with an associated documented coagulation abnormality.⁸⁹ FFP is often requested prophylactically before an invasive

procedure when the patient exhibits mild prolongation in coagulation studies. Most of these procedures may be carried out safely without transfusing FFP.^{87,90} A randomized trial of FFP versus no FFP in critically ill nonbleeding patients with INR between 1.5 and 3.0 scheduled to undergo central venous catheter placement, thoracentesis, percutaneous tracheostomy, or drainage of abscess or fluid is under way.⁹¹

Coagulation factors are normally present in the blood far in excess of the minimum levels required for hemostasis. As little as 10% of the normal plasma concentration of several factors will effect hemostasis. Conversely, FFP treatment of acquired multiple deficiencies, as in hepatic failure, is often ineffective because many patients cannot tolerate the infusion volumes required to achieve hemostatic levels of coagulation factors, even transiently.⁹² The plasma half-life of transfused factor VII is only 2 to 6 hours. It may be impossible to administer sufficient FFP every few hours without encountering intravascular volume overload. Finally, in some instances, transfusion of seemingly adequate volumes may still fail to correct the coagulopathy.⁹³ Careful documentation of both the need for FFP and the adequacy and outcomes of therapy is essential.⁹⁴

Transfusion of FFP is associated with significant adverse effects. It is the most commonly implicated blood product in the development of TRALI. Because of the large volumes that may be transfused, FFP administration is a risk factor for transfusion-associated circulatory overload (TACO). Allergic reactions to FFP are usually mild with the exception of anaphylactic reactions to IgA proteins that can occur when plasma is transfused in IgA-deficient patients.

CRYOPRECIPITATE

A total of 1.1 million units of cryoprecipitate were transfused in 2008 in the United States at a mean average cost of \$65.10/unit.¹ Cryoprecipitate is prepared by thawing and centrifuging FFP below 6°C and resuspending the precipitated proteins in a small volume of supernatant plasma. Each unit is a concentrated source of factor VIII (≥80 IU), von Willebrand factor (50% of original plasma content), fibrinogen (≥150 mg), factor XIII (30% of original plasma content), and fibronectin. It is considered to be leukoreduced without additional filtration. Cryoprecipitate offers the advantage of transfusing more specific protein and less total volume than an equivalent dose of FFP. Cryoprecipitate does not require crossmatching, but ABO compatibility with the recipient is preferred.

Indications for Cryoprecipitate Transfusion

In the past, cryoprecipitate was used to treat patients with inherited coagulopathies, such as hemophilia A, von Willebrand disease, and factor XIII deficiency. However, the availability of safer specific factor concentrates makes use of cryoprecipitate unwarranted for these conditions unless factor concentrates are unavailable. In the critical care setting, cryoprecipitate is most commonly used to replenish fibrinogen, especially in bleeding patients with hypofibrinogenemia caused by dilutional or consumptive coagulopathy. Transfusion of cryoprecipitate is usually recommended when fibrinogen levels are less than 100 mg/dL in the setting of bleeding or need for an invasive procedure.^{83,95,96} Cryoprecipitate also reportedly improves hemostasis in

uremic patients, presumably by reversing the functional platelet defect,⁹⁷ but desmopressin⁹⁸ or conjugated estrogens exert similar effects and should be used preferentially to avoid potential transfusion-related complications. Similar to other blood components, cryoprecipitate is often transfused inappropriately.⁹⁹

The usual dose of cryoprecipitate to treat hypofibrinogenemia is 10 units to start, then 6 to 10 units every 8 hours or as necessary to keep the fibrinogen level above 100 mg/dL. The fibrinogen response will depend on the patient's plasma volume (varies with gender and weight), initial fibrinogen level, and consumption of fibrinogen. A simple formula to start with dosing is number of units = $0.2 \times \text{weight (kg)}$.¹⁰⁰ Each unit of cryoprecipitate carries a risk of disease transmission equivalent to that of 1 unit of blood.

ADVERSE EFFECTS OF BLOOD COMPONENT TRANSFUSION

The decision to transfuse blood components must be made with full awareness of the potential risk to the recipient, as well as the expected benefits. For some patients, the benefit from transfusion of a blood product is so obvious that the associated risks are not significant in comparison to the consequences of withholding transfusion. However, the clinician's knowledge of the incidence and management of the adverse effects to transfusion is vital, not only to ensure the best patient care but also to provide appropriate patient education and true informed consent.

Measurable reactions to transfusion occur in about 20% of patients; more serious adverse responses may be expected in only 1% to 2% of transfusions.¹⁰¹ The nature of these adverse reactions ranges from those that are common but clinically unimportant to those that may cause significant morbidity or death. The Food and Drug Administration reported 58 transfusion-related or potentially transfusion-related deaths in 2011.¹⁰² From 2007 through 2011, TRALI accounted for 43% of fatalities followed by acute hemolytic reactions in 23%.

Why blood component transfusions may be harmful in critical care patients is not well understood. With the modern techniques in screening, storing, and matching RBCs, the mortality rate directly attributable to transfusions is extremely low; however, retrospective data often link increased numbers of transfusions to increased mortality rates.^{8,9,12,103} It is difficult to distinguish whether this trend is a function of anemia as a signal for increased severity of illness versus an actual consequence of the transfusion. Nevertheless, the relationship between transfusions and increased mortality rates is concerning, and a better understanding would help both clinicians and patients understand the risks involved with transfusions, as well as to aid investigators to develop new methods of safer transfusions. Potential mechanisms of recipient harm include risk of infections or multiorgan failure via immunomodulatory effects from the introduction during transfusion of unintended lipid breakdown products, cell-signaling factors, and donor-recipient antigen-antibody interactions.

ACUTE TRANSFUSION REACTIONS

The signs and symptoms of severe, life-threatening transfusion reactions are frequently indistinguishable from those of less significant reactions. However, every transfused patient who experiences a significant change in condition, such as an elevation in temperature, change in pulse or blood pressure, dyspnea, or pain, must be promptly and fully evaluated to identify the cause of the reaction and to institute treatment when necessary. The basic approach to all acute reactions should be to maintain a high index of suspicion for acute hemolytic reactions (with RBC components) by stopping the transfusion immediately, maintaining venous access with intravenous fluids, and informing the blood bank laboratory immediately so that the appropriate transfusion reaction protocol can be instituted and post-transfusion specimens obtained. Early recognition of severe transfusion reactions may be lifesaving.

ACUTE HEMOLYTIC TRANSFUSION REACTION

Acute hemolytic transfusion reactions (AHTRs) are caused by the recipient's existing complement-fixing antibodies attaching to donor RBC antigens with resultant intravascular RBC lysis. Non-ABO incompatibility is now more commonly implicated than ABO incompatibility in these incidents.¹⁰² In addition to hemolysis, complement activation stimulates the release of inflammatory mediators and cytokines and can lead to hypotension and vascular collapse. Activation of the coagulation system may result in DIC and bleeding. Acute renal failure may also occur, presumably on the basis of immune complex interactions. Morbidity and mortality rates are directly related to the quantity of incompatible blood transfused, which is why prompt recognition and cessation of transfusion are imperative. Misidentification of the patient, or clerical error, at any time beginning with acquisition of the donor specimen through release of the unit and initiation of infusion is the major cause of AHTRs.¹⁰⁴ It is preferable to transfuse uncrossmatched group O RBCs than to chance ABO incompatibility caused by improper patient and specimen identification procedures.

The most common clinical sign of an AHTR is sudden onset of fever, with or without chills.¹⁰⁵ Other common signs and symptoms include back or flank pain, anxiety, nausea, light-headedness, dyspnea, and hemodynamic instability. In a comatose or anesthetized patient, these symptoms may not be evident; therefore, signs such as hypotension, hemoglobinuria, and diffuse oozing from puncture sites or incisions may be the only notable features.

Immediate management of suspected AHTRs includes cessation of the transfusion; the remainder of care is supportive. Rapid verification of patient and unit identification must be made, not only to confirm the suspected reaction but also to prevent a second patient from receiving a reciprocally incompatible unit if a clerical error has been made. Steroids, heparin, or other pharmacologic interventions have no role in treatment.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

Febrile nonhemolytic transfusion reactions (FNHTRs) are the most commonly occurring acute reaction to RBC and

platelet transfusions. These reactions can cause significant discomfort and must be investigated because they share manifestations with AHTRs and bacterially contaminated blood. Although a temperature increase of 1°C is often used to define an FNHTR, fever may be absent in patients pretreated with antipyretics. Additional clinical signs include chills or rigors usually beginning 1 to 2 hours after the start of the transfusion but occasionally delayed up to 4 to 6 hours. Associated manifestations may include nausea, vomiting, and dyspnea. FNHTRs occur in approximately 1.0% of transfusion episodes but are more common with platelet transfusions (4-31%).^{106,107} The cause of FNHTRs varies with the transfused product, but the release or presence of cytokines and pyrogens results in the clinical manifestations. This reaction to RBC transfusion is usually initiated by the interaction of recipient antibodies to donor leukocytes. Nonhemolytic transfusion reactions (NHTRs) with platelet products are most commonly initiated by leukocyte- or platelet-derived cytokines or other biologic response modifiers.¹⁰⁷ Management of NHTRs includes discontinuation of transfusion and initiation of the appropriate transfusion reaction evaluation. Antipyretics such as acetaminophen may be administered. Antihistamines are neither preventive nor therapeutic. Once acute hemolysis is excluded, transfusion of a new unit may be instituted. If repeated NHTRs become problematic, leukocyte-depleted blood components should be supplied. The implementation of universal leukocyte reduction results in a reduction in the frequency of all fever seen after transfusion by only about 12%.¹⁰⁸ Pretreatment with antipyretics or corticosteroids may also minimize FHTRs.

ANAPHYLAXIS

Anaphylactic reactions to blood transfusions are rare but may be life-threatening. The usual cause is recipient antibody to a component of plasma that the patient lacks, most commonly antibody to IgA in IgA-deficient individuals. However, antibodies to other proteins (anti-haptoglobin) have been demonstrated and activated platelet membranes may also play a role.^{109,110} The highest rate of anaphylaxis occurs with platelets followed by FFP and RBCs. Signs and symptoms usually begin within minutes after transfusion is initiated and include severe anxiety, flushing, dizziness, dyspnea, bronchospasm, abdominal pain, vomiting, diarrhea, hypotension, and eventually shock. Fever and hemolysis do not occur. Management includes immediate cessation of transfusion and standard therapy for anaphylaxis. If anti-IgA antibodies are determined to be the cause of this reaction, the patient must receive blood components donated by IgA-deficient individuals or, if unavailable, specially prepared washed RBCs and platelet concentrates. Plasma-derived preparations, such as albumin, and immunoglobulins contain varying amounts of IgA and pose a substantial risk in these patients.

ALLERGIC AND URTICARIAL REACTIONS

Hives and pruritus are relatively common cutaneous adverse effects of transfusion and may occur with transfusion of RBCs, platelets, and FFP.¹⁰⁶ They are a hypersensitivity reaction localized to the skin, and their cause is unknown but may include both donor and recipient characteristics. These

reactions consist of localized or generalized urticaria beginning shortly after the start of transfusion without fever or signs or symptoms of anaphylaxis or hemolysis. The transfusion should be temporarily interrupted, and antihistamines administered. If the hives resolve in a short time, the same unit of blood may be cautiously restarted. If repeated urticarial reactions occur, premedication with antihistamines may be effective.

DELAYED HEMOLYTIC TRANSFUSION REACTIONS

Delayed hemolytic transfusion reactions (DHTRs) are an uncommon but probably underrecognized reaction to RBC transfusion that result from the stimulation of a primary or secondary (anamnestic) recipient antibody response to foreign RBC antigens. These antibodies are below the limit of detection at the time of transfusion but increase after transfusion. DHTRs typically occur 3 to 14 days after transfusion but may not be recognized because of the lack of a clear temporal association with transfusion. DHTRs are more likely in patients requiring frequent RBC transfusion.¹⁰⁶ Patients may be asymptomatic or experience fever, chills, and an unexplained decline in hematocrit.¹¹¹ Transient elevation in unconjugated bilirubin and lactate dehydrogenase may also occur. The diagnosis is established by a positive direct antiglobulin (Coombs) test resulting from recipient antibody coating donor RBCs. The specificity of the antibody is often against such RBC antigens as the Rh family, Kidd, Duffy, or Kell systems. Hemolysis may not occur, but if it does, it is likely to be extravascular and only rarely causes renal failure or DIC.

Prevention of these reactions is difficult. Alloimmunization to foreign RBC antigens occurs in approximately 1% of transfusions.¹⁰¹ Detection of delayed antibodies is the purpose for requiring a new blood bank specimen every 72 hours if the patient has recently been transfused. Permanent transfusion records should record the occurrence of delayed antibodies, even though they may not be apparent at a later crossmatch.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

TACO is estimated to occur in 1:100 to 1:10,000 transfusions and accounts for 15% of transfusion-related fatalities in the United States between 2007 and 2011.¹⁰² It is more likely to occur with RBC or FFP transfusion due to the higher volumes of these blood components.¹¹⁰ Aside from the inherent volume of the blood components, the concurrently administered normal saline adds to the volume load. Risk factors for TACO include older age, critical care patients, cardiac and renal dysfunction, chronic anemia, increased volume of blood products, and increased rate of transfusion. Clinical manifestations of TACO include dyspnea, orthopnea, cough, and worsening oxygenation due to hydrostatic pulmonary edema. Management options include slowing the rate of transfusion and administration of diuretics. Careful attention to transfusion requirements and the use of volume reduction maneuvers available to the transfusion service can help minimize volume overload in most instances. TACO may be difficult to distinguish

clinically from TRALI but TACO is less likely to be associated with fever and hypotension and more likely to be associated with a significantly elevated brain natriuretic peptide (BNP) and hypertension.

TRANSFUSION-RELATED ACUTE LUNG INJURY

TRALI is now the leading cause of transfusion-related deaths in the United States.¹⁰² An increase in incidence of TRALI is likely related to an increased awareness of the syndrome rather than a true increase in frequency of reactions. The reported incidence of TRALI for all blood component transfusions is less than 0.1%, but in the critical care setting, it is reported to be as high as 8% per transfusion.¹¹² Products containing plasma (e.g., FFP and platelets) appear to have the highest risk, but the reaction has been seen with all types of blood components. Transfusion of plasma from female donors also increases the risk of TRALI.^{112,113} TRALI is defined as the development of acute lung injury (hypoxia and bilateral infiltrates of noncardiac cause) within 6 hours of transfusion in the absence of another more likely cause.^{113,114}

In patients without prior respiratory compromise, TRALI manifests as acute hypoxia with the development of rales and diffuse infiltrates on chest radiograph.¹¹⁵ Recognition of TRALI may be difficult in critically ill patients who may have other reasons for dyspnea or may already require mechanical ventilation. In addition, TRALI and TACO may be difficult to distinguish. Clinical features that favor TRALI over TACO include the presence of fever and leukopenia. Hemodynamic monitoring may aid in differentiation, but is not required for management.

Unlike other forms of acute respiratory distress syndrome (ARDS), TRALI is usually self-limiting and resolves within 1 to 4 days. However, reactions can be severe, and often may necessitate mechanical ventilation. Treatment consists of supportive care, including the prompt management of hypoxia. If mechanical ventilation is required, lung protective ventilation should be implemented, and daily spontaneous breathing trials should be performed to ensure timely extubation upon resolution. Because the inciting factor is derived from the donor product rather than the patient, additional blood products can still be transfused if necessary with low risk of redevelopment.

Studies have suggested several mechanisms in the development of TRALI. The presence of leukocyte antibodies in the donor blood has been consistently linked to many cases, although other triggers such as lipids and biologic response modifiers (cytokines) have also been implicated.^{116,117,113} When exposed to donor antibodies, neutrophils that are already recruited to the pulmonary vascular endothelium release inflammatory products, leading to injury of the endothelial cells and increased vascular permeability. Recipient factors are also involved, as blood products from the same donor do not consistently cause TRALI in different recipients. Critically ill patients may be more susceptible to TRALI owing to increased localization of neutrophils in the pulmonary vasculature.

To reduce the risk of TRALI, blood agencies are evaluating possible interventions to reduce the presence of leukocyte antibodies in the donated products. One strategy is to limit donation by multiparous women, who are at high risk

of carrying antibodies.¹¹⁸ Decreasing the duration of storage of blood products may also be beneficial. The number of fatalities due to plasma has been decreasing in the United States, most likely due to reduced plasma transfusion from female donors.¹⁰²

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Transfusion-associated GVHD (TA-GVHD) is a rare and usually fatal immunologic complication of blood component transfusion.¹⁰⁶ Immunocompromised patients infused with blood components containing viable donor lymphocytes are at risk for engraftment of the allogeneic lymphocytes and ensuing rejection of recipient (host) tissues. Transfusion recipients who are at highest risk include bone marrow and organ transplant recipients, leukemia and lymphoma patients, and recipients of blood donated by relatives. TA-GVHD has been reported in patients after cardiac surgery who received designated donor blood from relatives; presumably, the HLA antigenic differences between donor and recipient were insufficient to stimulate a recipient immune response but sufficient to elicit a donor immune response.¹¹⁹ The onset of TA-GVHD is usually within 8 to 30 days after transfusion, and it is manifested as fever and skin rash, followed by diarrhea and evidence of liver dysfunction and bone marrow suppression. TA-GVHD differs from that seen in bone marrow transplantation (BMT) by its involvement of the marrow and far greater mortality risk. Treatment is largely ineffective, and mortality rate exceeds 90%.

Irradiation of blood components at 25 Gy prevents TA-GVHD by eliminating the donor lymphocyte mitogenic response. All cellular blood components should be irradiated before transfusion to high-risk patients. The functions of the cellular components of blood are unaffected, although damage to RBC membranes limits the duration of postirradiation storage of PRBCs to 28 days. Blood donated by a relative for any patient should be irradiated, as should HLA-matched or crossmatched platelet products.

TRANSFUSION-RELATED IMMUNOMODULATION

Transfusion-related immunomodulation (TRIM) may potentially have significant adverse effects that affect patient outcome. Allogeneic RBC transfusion has been shown to suppress the recipient's immune response, an effect first noted with kidney transplantation that resulted in increased survival of the transplanted kidney.¹²⁰ However, immunosuppression is generally undesirable in critically ill patients, even though the clinical impact of blood component transfusion is not well defined. As noted in previous sections, immunomodulation likely contributes to AHTRs, NHTRs, anaphylaxis, and TRALI. The major clinical issues regarding TRIM center around the association between blood product transfusion and increased risk of infection and increased and more rapid rates of tumor recurrence in surgical oncology patients. The largest prospective trial of colorectal cancer resection, for example, was negative,¹²¹ but a meta-analysis of existing data suggests that an adverse effect on recurrence does exist.¹²² Significant heterogeneity exists in the reported studies and makes definitive

conclusions difficult.¹²³ Most retrospective and prospective trials of postoperative or critical care unit infections suggest an adverse effect of blood component transfusion.¹²⁴⁻¹²⁶

The precise mechanism of the immunomodulation induced by transfusion has not yet been delineated, and several mechanisms may be involved.¹²³ Allogeneic plasma, leukocytes and substances that accumulate in stored blood components may contribute to TRIM. Alterations identified in laboratory and clinical transfusion recipients have included depression of the T-helper/T-suppressor lymphocyte ratio, decreased natural killer cell activity, diminished interleukin 2 generation, formation of anti-idiotypic antibodies, impairment of phagocytic cell function, and chronic persistence of donor lymphocytes (microchimerism), suggestive of low-level GVHD. Difficulties in analysis of human data arise because patients requiring blood component transfusions have conditions that may induce immune changes. There is some evidence from two large clinical trials to suggest that leukocyte reduction of blood components reduces or eliminates this immunomodulatory effect but other results are conflicting.^{127,128} Well-designed prospective trials are needed to more clearly elucidate the impact of any immunomodulatory effects of transfusing blood products.

TRANSFUSION-TRANSMITTED INFECTIOUS DISEASES

Transfusion-associated acquired immunodeficiency syndrome (AIDS) has done more to revolutionize transfusion practice than any other transfusion risk by resulting in more conservative blood use, more stringent donor selection criteria, and improved screening tests. The result is that viral transmission rates are now difficult to measure, and the risk of transfusion-related infectious diseases is lower than ever.^{46,129} Bacterial infection has become the most common infectious risk.

MICROBIAL AND ENDOTOXIN CONTAMINATION

Several fatalities are reported yearly from the transfusion of blood components contaminated with viable bacteria, with or without the accumulation of endotoxin.^{102,130} Platelet concentrates stored at room temperature are particularly prone to bacterial growth, with a reported incidence of 1.13 in 10,000 components with apheresis units having the highest contamination rate.¹³¹ Organisms isolated from platelets and implicated in fatal transfusion reactions include *Staphylococcus* and *Streptococcus* species and gram-negative bacilli. Fatalities resulting from bacterial contamination of refrigerated RBCs have occurred as well and more often involve cryophilic bacteria. RBC transfusions contaminated by *Yersinia enterocolitica* have been consistently reported for a decade.¹³² Transfusion reactions caused by bacterial or endotoxin contamination are fortunately quite rare, but the mortality rate exceeds 60%.

Signs and symptoms of reactions caused by microbial contamination overlap those of hemolytic transfusion reactions and consist primarily of fever and hypotension, along with other signs of endotoxic shock. A Gram stain of the implicated unit can be prepared immediately and, if positive, appropriate antibiotic and supportive therapy instituted. Autologous blood components may also be contaminated at

the time of collection; therefore, reactions occurring in patients who are receiving their own blood should be evaluated as fully as though they were receiving allogeneic blood.

HEPATITIS

The success of viral screening measures is most clearly illustrated by the fall in the risk for posttransfusion hepatitis over the past 2 decades. The elimination of paid donors in 1972 and the introduction of nucleic acid tests for hepatitis B virus (HBV) and hepatitis C virus (HCV) have resulted in a steady reduction in the rates of posttransfusion hepatitis. The estimated residual risk for HBV is 1 in 2.8 million to 1 in 3.6 million transfused blood components.¹³³ Although about 30% to 40% of HBV transmissions will result in acute hepatitis, chronic HBV infection develops in less than 10% of such patients. In contrast, the risk for chronic HCV infection after transfusion is higher, nearly 50%, and the long-term risk for mortality related to cirrhosis or hepatocellular carcinoma is about 15% over more than 20 years after posttransfusion hepatitis secondary to HCV.^{134,135} The risk of HCV transmission is even lower than HBV with a residual risk estimate of 8.7 per 10 million transfused blood components.¹³⁶ The clinical course of hepatitis A is generally milder, and the lack of a chronic carrier state means that with donor screening for symptoms of the acute illness, the risk of transmission is rare.

RETROVIRUSES

Retroviruses known to be capable of transmission by transfusion are human immunodeficiency virus (HIV-1, HIV-2) and human T-cell leukemia/lymphoma virus (HTLV I and II). Transfusion-associated AIDS was initially reported in late 1982.¹³⁷ The first report of an associated viral agent did not appear until late 1983, and in March 1985 the screening enzyme-linked immunosorbent assay (ELISA) to detect antibody to HIV-1 was licensed and immediately incorporated into the blood-screening process. Improved confidential donor screening also decreased the risk of infectious units appearing in the donor pool.¹³⁸ The discovery that heat treatment decreased transmission resulted in a reduction in transmission by plasma products, especially to persons with hemophilia. Removal of donor units with seropositivity by ELISA was insufficient to prevent transmission of HIV-1. Subsequent development of an assay for the p24 antigen and nucleic acid testing have lowered the risk of transfusion-associated HIV-1 infection to an estimated 1 in 1,467,000 transfused blood components.¹³⁶ Despite donor screening and sensitive assays, an extremely small but finite risk of HIV-1 transmission by screened blood transfusions remains. This risk is largely due to the eclipse period (interval between infection and development of detectable concentrations of HIV RNA in plasma) experienced by newly infected donors. The eclipse period for HIV-1 is estimated to be 9 days.¹³⁶

A second retrovirus, HIV-2, first described in residents of countries in West Africa and subsequently detected in migrants to western Europe, causes an immunodeficiency syndrome similar to that caused by HIV-1. Although very few cases of HIV-2 have been reported in the United States¹³⁹ and there have been no reported transfusion-transmitted cases, experience with other retroviruses suggests that screening may prevent the majority of potential

transmissions. Therefore, donated blood is now screened for the presence of HIV-2.

The retrovirus HTLV-I is the causative agent of adult T-cell leukemia (ATL) and is strongly implicated in the chronic, progressive neurologic disorder termed *tropical spastic paraparesis* or *HTLV-I-associated myelopathy* (TSP/HAM). HTLV-II has been linked to hairy cell leukemia, but no transfusion-transmitted cases have been reported. The virus exhibits strong serologic cross-reactivity with HTLV-I such that screening assays fail to distinguish between the two viruses. Transfusion-transmitted HTLV-I has been demonstrated.¹⁴⁰ TSP/HAM has developed in a small percentage of infected transfusion recipients, but no transfusion-associated cases of ATL have been seen. Approximately 0.025% of donors in the United States are seropositive for HTLV-I and HTLV-II¹⁴¹; further testing reveals the majority of them to be HTLV-II. Donated blood is currently screened for antibodies to HTLV-I and HTLV-II.

CYTOMEGALOVIRUS

CMV is a human herpesvirus that establishes latent infection in the host's tissues, particularly leukocytes, and is transmitted by all cellular blood components.¹⁴² Seropositivity, or the presence of antibody, denotes previous exposure to the virus but does not confer protective immunity. Secondary reinfection or reactivation of latent infection can occur. Antibodies to CMV persist for life and serve as a marker indicating the potential for transmission of live virus.

Immunocompetent recipients of transfused CMV-positive blood experience minimal morbidity and mortality risks. The majority are asymptomatic, whereas a heterophile-negative mononucleosis syndrome may develop in a few. Immunocompromised patients, however, may suffer life-threatening manifestations such as severe interstitial pneumonitis, gastroenteritis, hepatitis, or disseminated disease. Several groups of patients are at particular risk (Box 79.4),¹⁴³ and these patients should receive blood incapable of transmitting the virus. Screening of donated blood for CMV is not routine but can be performed quickly if necessary. Because the prevalence of donor seropositivity is quite high, CMV-seronegative blood may not be readily available. Blood that is leukocyte depleted may be as effective as seronegative blood in the prevention of CMV transmission, although a meta-analysis of clinical trials comparing the two methods suggests that CMV-negative blood products might have a slight advantage over leukocyte-depleted products.¹⁴⁴

PARASITES

Many blood-borne parasites may be transmitted by transfusion, although this is a rare occurrence in the United States

because of donor screening questions and the low endemicity of implicated agents. Changing immigration patterns and global travel, however, make transfusion-transmitted parasites an increasing concern.

On a worldwide basis, malaria is the most important transfusion-transmitted infective parasite, although only a few cases are reported in the United States each year.¹⁴⁵ Such infections are manifested by delayed fever, chills, diaphoresis, and hemolysis, often masked by underlying medical conditions. Fatalities have occurred. Babesiosis, a tick-borne disease caused by *Babesia microti*, is endemic in regions of the northeastern United States. Transfusion-transmitted cases have been reported, with asplenic, elderly, or immunocompromised patients being particularly susceptible.¹⁴⁶ Babesiosis was the leading cause of infectious transfusion-related fatality in the United States from 2007 to 2011, and there are no effective methods of donor screening or testing.¹⁰² With increases in the number of Central and South American immigrants to North America, Chagas' disease, transmitted by the protozoan parasite *Trypanosoma cruzi*, has emerged as a potential transfusion-transmissible infection.¹⁴⁷ Other parasitic diseases that have been transmitted by transfusion include toxoplasmosis, leishmaniasis, and Lyme disease.

EMERGING INFECTIONS IN TRANSFUSION MEDICINE

Human parvovirus B19 has been recognized as a pathogen capable of transmission by transfusion, with typical clinical findings and the potential for aplastic anemia. Epstein-Barr virus infection with a typical mononucleosis-like illness has been reported after transfusion. West Nile virus can also be transmitted by transfusion. H2N1 influenza, severe acute respiratory syndrome (SARS), and other new viral infections should be capable of transmission by transfusion, although cases have not been reported and the prevalence of asymptomatic disease is unknown. A rising concern is the transmission of prion disease, either Creutzfeldt-Jacob disease or bovine spongiform encephalopathy (BSE). Donor referral criteria were implemented in 1987 for these diseases, and transfusion transmission of BSE has been reported in the United Kingdom.

SPECIAL TRANSFUSION SITUATIONS IN THE CRITICAL CARE SETTING

MASSIVE TRANSFUSION

Massive transfusion is commonly defined as the administration of blood components in excess of one blood volume or greater than or equal to 10 units PRBCs within a 24-hour period, although other definitions have been used in the literature and for resuscitation protocols.¹⁴⁸ Massive transfusion, especially in the range of 20 or more units of blood products, causes complications not generally seen in usual transfusion practice: accumulation of undesirable substances present within stored blood and dilutional depletion of normal blood constituents that are lacking in stored units. Trauma victims, surgical patients undergoing complex or emergent procedures, and patients with vascular or coagulation disorders may require massive transfusion in the critical care setting. The first priority in such patients is to

Box 79.4 Patients for Whom Cytomegalovirus-Safe Blood Components Are Strongly Recommended

- Seronegative pregnant women
- Seronegative premature infants weighing less than 1200 g
- Seronegative allogeneic or autologous bone marrow transplant recipients
- Seronegative transplant recipients of seronegative organs

stop the bleeding but transfusion of blood products occurs simultaneously to maintain hemostasis and ensure oxygen-carrying capacity. Survival is determined more by the nature and degree of the patient's injuries or medical conditions than by the transfusions, but the presence of adverse effects of massive transfusion can complicate a patient's course in the ICU.

Transfusion of large quantities of RBCs deficient in functional platelets often results in hemostatic defects and thrombocytopenia. Platelet counts consistently decrease in inverse proportion to the amount of blood administered, with the hemostatically significant level of $50 \times 10^9/L$ reached after 20 units.¹⁴⁹ Functional defects have also been noted.¹⁵⁰ Despite these laboratory changes, severe diffuse bleeding develops in less than 20% of massively transfused patients, and no laboratory studies alone are predictive. Prophylactic platelet transfusions were not shown to be of benefit in older studies.¹⁵¹ Platelet counts may return to hemostatically effective levels quickly in patients with normal marrow function.

Resuscitation of massively bleeding patients with PRBCs in combination with crystalloids will usually result in hemodilution to about 60% of normal coagulation factor levels after the transfusion of about 10 units; this factor level can usually maintain normal hemostasis. However, if crystalloids are given in excess of PRBCs less plasma protein may remain after 10 units are transfused. Bleeding is unlikely until prothrombin time (PT), INR, and PTT prolongations exceed 1.5 to 1.8 times the midpoint normal range, the equivalent of an INR approaching 2.0.¹⁴⁹ Prophylactic administration of FFP was also not effective in preventing diffuse bleeding in older studies.¹⁵² Based on the earlier studies, previous recommendations suggested that transfusion of blood components in massive bleeding should be based on measured or anticipated results of platelet count and coagulation studies (laboratory driven).

More recently some trauma centers have adopted a protocol approach (formula driven) to replacing platelets and plasma when massive transfusion is required, usually with a set ratio of RBC to platelet and FFP infusions (e.g., 3:1:1 or less).^{153,154} Variable ratios have been used and the optimal ratio of blood products is not defined. Although the published experiences from these retrospective, nonrandomized studies are generally positive, confirmation is needed from well-designed prospective randomized studies to avoid bias, particularly survival bias that favors higher plasma to RBC ratios.^{155,156} Additional reports have also suggested that early transfusion of FFP may not improve outcomes and may predispose to organ failure.^{157,158} Until higher quality evidence can support the use of specific blood product ratios in massive transfusion, it is difficult to support this practice.

Blood preservative solutions contain citrate, which anticoagulates stored blood by binding ionized calcium. WB contains approximately 1.8 g of citrate/citric acid per unit in the plasma fraction. Patients with normal liver function can metabolize the citrate load in 1 unit of WB in 5 minutes, but hepatic impairment may extend removal to 15 minutes or longer. Toxicity may result when citrate is administered in excess of the metabolic capacity, thereby causing a decrease in ionized calcium levels.¹⁵⁹ Although paresthesias, cramps, and myoclonus can result from citrate excess, the principal danger of hypocalcemia is depression of

myocardial contractility and potential prolongation of the QT interval. Because the effects of citrate are transient and the use of PRBCs containing little residual citrated plasma is far more common than massive transfusion with WB, routine administration of calcium is not indicated; clinically significant rebound hypercalcemia may result. Calcium infusion should be limited to hypoperfused patients with hepatic or cardiac failure who manifest citrate toxicity. Hypomagnesemia is common in patients with massive transfusion, and it is often associated with hypocalcemia.¹⁶⁰ Citrate binds magnesium as well as calcium and may play a role in the development of hypomagnesemia.¹⁴⁸ Hypomagnesemia does not appear to impact outcomes in massively transfused patients.

Potassium leaks from RBCs during storage, and up to 7 mEq of extracellular potassium may accumulate in each unit. Irradiation of RBCs increases extracellular potassium. However, dangerous levels of potassium rarely develop in adults from transfused blood; the potassium level is more likely to be determined by the patient's acid-base status.¹⁶¹ Studies of massively transfused patients have demonstrated a wide range of potassium levels, with hypokalemia seen as frequently as hyperkalemia. Because of the complexity of physiologic changes during resuscitation, it is impossible to predict the net effect of massive transfusion on serum potassium levels. Potassium levels need to be monitored closely in patients receiving large amount of PRBCs.

The pH of stored blood drops during storage, from 7.16 at the time of collection to as low as 6.73 after several weeks of storage. The administration of large quantities of acidic blood, together with the metabolic acidosis common in these patients before resuscitation, would lead one to expect worsening acidosis as the outcome of massive transfusion. However, patients are more likely to exhibit metabolic alkalosis at the end of the transfusion episode,^{161,162} partly because of improved tissue perfusion and the metabolism of citrate and lactate to bicarbonate. Patients in renal failure may be unable to handle the bicarbonate load and require dialysis. Acidosis persisting after transfusion suggests inadequate tissue perfusion.¹⁵⁹ Empiric administration of bicarbonate to counter the acid load is not warranted and may contribute to the deleterious effects of hypercapnia in patients with impaired ventilation.

RBC components are stored at approximately 4°C and require 30 to 45 minutes to warm to room temperature. Elective transfusions at standard flow rates are tolerated without the need to warm the blood; however, core body temperature, measured by esophageal probe, can fall to 30°C or lower with the administration of large volumes of cold blood over a period of 1 to 2 hours.¹⁶³ Adverse effects of hypothermia include a decreased heart rate and myocardial contractility, cardiac arrhythmias, increased affinity of hemoglobin for oxygen resulting in decreased tissue oxygen delivery, DIC, and impaired ability to metabolize the citrate load of stored blood. Both blood warmers and patient warming may be instituted during massive transfusion, and patient core temperature should be monitored during resuscitative efforts.

Whether massive transfusion in and of itself is a cause of ARDS is another source of controversy. There are theoretical reasons why massive transfusion might precipitate ARDS because all cellular transfusions contain damaged or activated WBCs, cell membranes, aggregated platelets, and

microthrombi, all of which are capable of lodging in and damaging pulmonary capillaries. Despite this possibility, neither microfiltration of transfusions nor routine leukocyte depletion has shown a significant impact on the incidence of ARDS in massively transfused patients.¹⁶⁴ Certainly, other causes of ARDS exist in patients who undergo massive transfusion, and the possibility of TACO and TRALI should be considered in the evaluation of patients with hypoxia and diffuse pulmonary infiltrates after massive transfusion.

AUTOIMMUNE HEMOLYTIC ANEMIA

Patients with autoimmune hemolytic anemia (AIHA) have an autoantibody, usually of broad specificity, that fixes itself to their RBCs and triggers extravascular immune-mediated destruction. Patients with AIHA have a positive direct antiglobulin test (DAT, commonly known as the Coombs test)¹⁶⁵ and varying degrees of hemolysis, and their autoantibodies cause agglutination of RBCs from all donors during cross-matching. If the hemolysis is brisk, patients may require RBC transfusion to support oxygen needs before medical management is effective. Hence, transfusion is difficult because agglutination during crossmatching interferes with proper definition of compatible units of RBCs and because the transfused RBCs are themselves subject to the same immune hemolysis as the host RBCs. Many blood banks have methods for depletion of autoantibodies from the recipient's plasma and elution of antibodies from RBCs to arrive at a proper crossmatch.¹⁶⁶ Although such crossmatches are time consuming and not generally available on an emergency basis, they can be lifesaving. Criteria for transfusion should remain the same as for other recipients.

NECESSARY TRANSFUSION OF INCOMPATIBLE BLOOD

RBCs are crossmatched for RBC antigens in the ABO and Rh₀(D) group and for other RBC antigens when antibodies are present. However, there are several hundred other RBC antigens in the human family and with repeated transfusion recipients may become alloimmunized to other antigens. Generally, alloimmunization occurs in approximately 1% of transfusions, but the prevalence of alloantibodies is higher in chronically transfused, relatively immunocompetent patients, especially African Americans, whose distribution of RBC antigens has significant variation from the white population. Alloimmunization may present difficulties in cross-matching of blood to the point that compatible blood must be obtained from rare-donor registries, if at all. In some patients the alloantibody is never precisely identified, yet the majority of blood available for transfusion is incompatible. The delay engendered by working with multiple or unidentified antibodies may be unacceptable in some critical care situations in which the need for oxygen-carrying capacity leaves no choice but to transfuse incompatible blood. The behavior of these antibodies in the laboratory may assist in predicting the clinical outcome of the incompatible transfusion.¹⁶⁷ Special procedures such as clearance studies, flow cytometry, and in vivo crossmatching (cautious administration of a small aliquot of blood, with subsequent observation of serum and urine for evidence of hemolysis) are useful if time permits.

Emergency transfusion of type O, Rh-negative uncross-matched blood is generally reserved for the resuscitation of trauma patients, for whom the delay in crossmatching may be life-threatening. The risks of alloimmunization to non-ABO antigens are generally accepted as low and a recent study found antigen-incompatible RBCs were transfused in 2.6% of patients who required emergency blood release.¹⁶⁸ Even Rh-positive type O RBCs may be used because rates of alloimmunization to Rh₀(D) are low under the circumstances of emergency transfusion.

TRANSFUSION IN PATIENTS WITH DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a common disorder in critically ill patients that may manifest as severe hemorrhage or thrombosis. Therapy is primarily directed at treating the cause and supporting the patient. Supportive therapy includes the transfusion of blood components needed to correct the bleeding diathesis caused by the consumption of platelets and fibrinogen, in addition to PRBCs to restore oxygen-carrying capacity. Platelets and fibrinogen (as cryoprecipitate) are the most common components used to treat the coagulopathy, but their use risks increasing the microvascular thrombosis of DIC. Heparin anticoagulation is controversial and may increase the risk of bleeding, especially if depleted factors are not replenished. No clinical trials support the routine use of heparin, and randomized trials of other components and coagulation inhibitors have uniformly been negative.

HEPATIC FAILURE

Cirrhotic patients or those with fulminant hepatic failure have a variety of hemostatic disorders that complicate transfusion management of a bleeding patient.¹⁶⁹ Hepatic synthesis of coagulation factors may be markedly diminished, thereby necessitating replacement by FFP or cryoprecipitate. Patterns of factor diminution may vary between acute hepatic necrosis and chronic cirrhosis.¹⁷⁰ Associated hemodynamic alterations may make it impossible to administer the volumes required for effective hemostasis, however, and any effect is transient. The use of factor concentrates or antifibrinolytic agents may precipitate thrombosis. Activation of fibrinolysis and decreased clearance of activated factors may produce or mimic chronic DIC, thus further exacerbating the factor deficiencies and impairing coagulation. Abnormal platelet function and thrombocytopenia may contribute to the coagulopathy of liver disease, with concomitant splenomegaly reducing the effectiveness of platelet transfusions. As with DIC, blood product transfusions for coagulopathy of hepatic failure have not demonstrated any long-term benefits, and should be considered only to achieve emergent hemostasis.

ALTERNATIVES TO TRANSFUSION OF BLOOD COMPONENTS

The safest transfusion is one that is not given. Therefore, alternatives to blood component therapy continue to be sought. It may be possible to limit blood component expo-

sure by the appropriate use of pharmacologic agents that promote hemostasis and the administration of recombinant hematopoietic growth factors to stimulate marrow hematopoiesis.

BLOOD SUBSTITUTES

Two types of alternative oxygen carriers are being evaluated for clinical use, but no oxygen-carrying blood substitute is currently approved for use in the United States.^{171,172} Perfluorocarbons are hydrophobic molecules with high oxygen-carrying capacity that have to be administered as an emulsion to be soluble in plasma. The perfluorocarbon solutions have failed to demonstrate any utility as intravascular oxygen carriers because of their unfavorable P-50 (oxygen half-saturation pressure) and oxygen off-loading characteristics. The other type of preparation that has been explored in clinical trials is cell-free hemoglobin solutions cross-linked or polymerized by chemical manipulation to prevent rapid clearance from the circulation. Known as hemoglobin-based oxygen carriers (HBOCs), they are intended to provide short-term oxygen-carrying capacity for acutely ill patients and have the advantage of not requiring cross-matching and no risk of infection. Although these proposed products may have a longer shelf-life and are easier to transport, they have many drawbacks. Most have a circulatory half-life of only about 24 hours. The oxygen dissociation curve for these substitutes is also frequently not favorable: either a high FIO_2 is required to “load” these molecules or they are less likely to deliver oxygen efficiently at lower PO_2 levels. Certain preparations of HBOCs are currently in clinical trials. Main concerns for HBOCs have been unfavorable side effects including hypertension, increased cardiovascular mortality risk, and renal dysfunction. Because the hemoglobin source is reclaimed bovine or human RBCs, it is unlikely that patients who do not accept blood components because of their religious beliefs (Jehovah’s Witnesses) will accept these types of hemoglobin solutions.

DESMOPRESSIN

The synthetic vasopressin analog, desmopressin (DDAVP), increases plasma factor VIII:c and promotes the release of von Willebrand factor from endothelial stores.¹⁷³ DDAVP has provided effective hemostasis in bleeding patients with mild hemophilia A and type I von Willebrand disease and has been used as prophylaxis for patients undergoing surgery. DDAVP reportedly improves platelet function in some patients with qualitative platelet disorders associated with uremia, cirrhosis, and aspirin ingestion. Studies of its efficacy in cardiopulmonary bypass procedures are conflicting, but a subset of these patients may benefit. The chief drawback to its use is tachyphylaxis, which develops in essentially all cases after short-term repeated administration.

ANTIFIBRINOLYTIC AGENTS

The lysine analogs ϵ -aminocaproic acid and tranexamic acid inhibit fibrinolysis by blocking the binding of plasminogen and plasmin to fibrin. These antifibrinolytic agents may decrease bleeding and thus the need for homologous blood

components in patients with hemophilia, thrombocytopenia, and systemic fibrinolysis. A novel and effective use of tranexamic acid involves administration as a mouthwash in preparation for oral surgery in patients with hemophilia or those receiving oral anticoagulant therapy. Tranexamic acid has also been demonstrated to effectively decrease mortality rates in high-risk trauma patients when given at presentation.¹⁷⁴ Use may also be promising in decreasing blood transfusion requirements in high-risk surgical procedures, such as radical prostatectomy.¹⁷⁵ The most serious side effect of these agents when systemically administered is thrombosis; thus, it is important to use them appropriately and monitor the patient carefully during their use.

Aprotinin is a naturally occurring bovine serine protease inhibitor that acts on plasma serine proteases such as plasmin, kallikrein, trypsin, and some coagulation proteins. Aprotinin was previously shown to reduce blood loss in patients undergoing cardiopulmonary bypass surgery by inhibiting fibrinolysis and preventing platelet damage.¹⁷⁶ However, an observational study and a large multicenter randomized trial in cardiovascular surgery patients found that use of aprotinin was associated with an increased mortality rate, and therefore should not be used routinely.^{177,178}

VITAMIN K

When time permits, vitamin K is the preferred agent to reverse the coagulopathy induced by warfarin. Normalization of the PT can be seen in as few as 6 to 12 hours. Additionally, selected cirrhotic patients may exhibit improvement in the PT when treated with therapeutic doses of vitamin K. Many patients in critical care units exhibit a prolonged PT, especially if dietary supplements are limited and broad-spectrum antibiotic therapy is given. Vitamin K is a safe and effective agent for reversing this effect. Intravenous administration of vitamin K is associated with a small risk of anaphylaxis, and oral replacement is preferred over subcutaneous administration for more consistent absorption.

HEMATOPOIETIC GROWTH FACTORS

Recombinant erythropoietin (EPO) has dramatically reduced the RBC transfusion requirements of patients with chronic renal failure, in which decreased renal EPO production accounts for the anemia. Studies of EPO efficacy in reducing perioperative RBC transfusion requirements by increasing the yield of predeposited autologous blood or stimulating bone marrow synthesis after surgery have shown benefit in reducing blood transfusion, although preoperative planning and autologous deposits are required.¹⁷⁹ Despite initial promising results, use of EPO in critically ill patients lacked efficacy in decreasing RBC transfusions and increased the risk for thrombotic vascular events.¹⁸⁰ Consideration for EPO administration may be appropriate in select patients who are unable to receive blood transfusions after risks and benefits are addressed.

CELL SALVAGE TECHNOLOGY

Cell salvage equipment has been in clinical use for several decades, and although cell salvage is clearly capable of rescuing otherwise “lost” RBCs, its full impact on transfusions

has been poorly documented. Cell salvage generally consists of collection of shed blood from a clean, uncontaminated operating field, followed by removal of the cellular elements and retransfusion into the patient. Cell salvage has been used both intraoperatively and postoperatively, especially in cardiac surgery. Although clinical studies of cell salvage have many methodologic flaws, it does reduce the need for blood transfusion in adult elective cardiac and orthopedic surgery.¹⁸¹ Risks include bacterial contamination, febrile reactions, triggering of DIC, and coagulopathy as a result of dilution. When combined with acute intraoperative hemodilution, this technology is also potentially cost saving.¹⁸²

LEGAL ISSUES IN TRANSFUSION MEDICINE

Most states regulate blood banking and medical practice, but blood products are regarded as a service, not as a commodity, so standard product liability does not pertain to blood components.¹⁸³ However, negligence in the course of preparing, testing, transferring, crossmatching, and administering blood products is still a potential cause for legal action. Every clinician who orders transfusions must be aware that blood components, like drugs, are approved for specific uses and that the indications should be clearly documented in the medical record.

The informed consent of the patient is an important area of potential liability. The Joint Commission has required written patient consent for blood transfusions since 1996. What constitutes adequate informed consent and who is responsible for advising the patient are still debated. Elements of informed consent include an understanding of the need for transfusion, its risks and benefits, and the alternatives, including the risk of not undergoing transfusion, as well as the opportunity to ask questions. Whether the clinician documents informed consent with an individual progress note in the patient record or with a standardized form is generally established as institutional policy. Similarly, institutions vary with respect to policies for consenting adults who are temporarily incompetent, such as sedated patients in the ICU.

A competent adult patient may refuse blood transfusion, and Jehovah's Witnesses commonly do so for religious reasons. Case law is clear in upholding this right of the patient,¹⁸⁴ which extends to care given at such time as the patient may become incompetent (i.e., comatose) after such refusal was expressed before becoming incompetent. Courts will usually order a lifesaving transfusion for minors. Exceptions have been made in the case of some "emancipated minors" who are at the age of reason. Most states have evoked a "special interest" in the welfare of a fetus in ordering transfusions to pregnant women.

The advent of sentinel event reviews and other quality management procedures for patient safety has had an impact on transfusion practice as well. Procedures for patient identification before surgical procedures, including devices such as bar code readers, have also been applied to transfusion practice.

KEY POINTS

- Blood components should be prescribed like therapeutic agents as part of a blood management program.
- RBC transfusion can be considered when the hemoglobin is less than or equal to 7 g/dL for the majority of hemodynamically stable ICU patients. A transfusion threshold of less than 8 g/dL may be appropriate for patients with symptomatic cardiovascular disease and postoperative surgical patients.
- Platelet transfusions are indicated for patients who have active bleeding due to thrombocytopenia or functional platelet defects and for the prevention of bleeding due to thrombocytopenia.
- FFP is indicated for the repletion of coagulation factors in bleeding patients deficient in those factors or to provide specific plasma proteins that cannot be obtained from safer sources.
- Cryoprecipitate is a concentrated source of fibrinogen and selected coagulation factors. Cryoprecipitate may be more helpful than FFP in correcting the hypofibrinogenemia of dilutional or consumptive coagulopathy.
- Adverse reactions to blood components occur in 1% to 2% of transfusion episodes. Adherence to routine protocols for the evaluation of transfusion reactions may save lives.
- Transmission of infectious agents by transfusion has been markedly reduced, and bacterial infection is now the most common infectious complication of transfusion.
- Adverse effects unique to massive transfusion are likely to complicate the management of critically ill or severely injured patients. Component therapy for such patients should remain conservative pending the outcome of prospective studies.
- Informed consent for blood transfusion is a standard of practice. A competent adult has the legal right to refuse blood transfusion.

Intensive Care of the Cancer Patient

Brendan D. Curti | Dan L. Longo

CHAPTER OUTLINE

METABOLIC AND ENDOCRINE COMPLICATIONS

Tumor Lysis Syndrome
Hypercalcemia
Oncogenic Osteomalacia
Syndrome of Inappropriate Secretion of Antidiuretic Hormone
Adrenal Failure
Pheochromocytoma
Tumor-Induced Hypoglycemia
Chemotherapy-Induced Metabolic Disturbances

CARDIAC COMPLICATIONS IN CANCER PATIENTS

Superior Vena Cava Syndrome
Cardiac Tamponade
Treatment-Induced Cardiac Dysfunction

PULMONARY COMPLICATIONS IN CANCER PATIENTS

Lymphangitic Tumor Involvement
Treatment-Induced Pulmonary Dysfunction
Diffuse Interstitial Pneumonitis
Hemoptysis

INFECTIOUS COMPLICATIONS IN CANCER PATIENTS

Febrile Neutropenia and Septic Shock

NEUROLOGIC COMPLICATIONS IN CANCER PATIENTS

Spinal Cord Compression
Brain Metastases and Hemorrhage
Uncontrolled Seizures

GASTROINTESTINAL COMPLICATIONS IN CANCER PATIENTS

Tumor-Induced Emergencies
Chemotherapy-Induced Gastrointestinal Dysfunction

Gastrointestinal Lymphomas

GENITOURINARY COMPLICATIONS IN CANCER PATIENTS

Tumor-Induced Genitourinary Dysfunction
Chemotherapy-Induced Genitourinary Complications

HEMATOLOGIC COMPLICATIONS IN CANCER PATIENTS

Hyperleukocytosis
Disseminated Intravascular Coagulation

BIOLOGIC THERAPY

Interleukin 2
Allergic and Anaphylactic Reactions to Monoclonal Antibodies

Immune-Mediated Toxicities from T-Cell-Directed Therapy

SPECIAL CONSIDERATIONS IN BONE MARROW TRANSPLANTATION

Acute Graft-Versus-Host Disease
Veno-occlusive Disease

Infectious Complications of Stem Cell Transplantation

CODE STATUS AND INTENSIVE CARE IN CANCER PATIENTS

SUMMARY

The annual estimated incidence of new invasive cancers in the United States in 2012 exceeds 1.6 million, with greater than 570,000 deaths.¹ Long-term remissions and control of advanced cancer are being achieved with targeted therapy, and new immunotherapy agents in many malignancies.²⁻⁶ We are entering an era of “personalized” oncologic care in which treatments are prescribed based on the profile of

mutated or overexpressed genes in the tumor specimen. For the treatment of metastatic malignancies, enhanced success has come from the ability to deliver chemotherapy, radiation therapy, immunotherapy, or combination regimens with increased dose intensity. Progress in supportive care and intensive care medicine has allowed oncologists to treat their patients aggressively and support them despite the

toxicities inherent in dose-intense treatment modalities. A greater understanding of the mechanisms for these toxicities has also improved care and patient outcomes.

This chapter describes specific oncologic clinical entities and cancer treatment toxicities that require intensive care management. The discussion of these problems is organized according to organ system because cancers are best understood as systemic diseases that can directly or indirectly influence all organ systems. The pathophysiology that gives rise to these clinical circumstances is increasingly understood and is used as the basis for treatment recommendations. Aspects unique to biologic therapies and bone marrow transplantation are treated in separate sections. The ethical aspects of treating cancer patients in the intensive care unit (ICU) are also discussed.

METABOLIC AND ENDOCRINE COMPLICATIONS

Endocrine syndromes associated with malignancies have been described for many years and some clinically significant endocrinopathies are induced by immunotherapy agents, such as ipilimumab, currently used in the treatment of advanced melanoma.^{4,7} These problems may manifest as solitary laboratory derangements, such as hypercalcemia or hyperphosphatemia, or can present as clinical syndromes, such as Cushing syndrome in small cell lung cancer. Metabolic disorders can also arise as a consequence of cancer treatment. This is most often seen with chemotherapy for rapidly growing tumors such as leukemias or lymphomas. Abrupt changes in metabolic variables have also been observed after interleukin 2 (IL-2)-based immunotherapy and the rapid in vivo expansion of lymphocytes.⁸ The most common of these clinical entities are tumor lysis syndrome (TLS), hypercalcemia, oncogenic osteomalacia, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), adrenal failure, pheochromocytoma, tumor-induced hypoglycemia, and chemotherapy-induced metabolic disturbances.

TUMOR LYSIS SYNDROME

Case reports of metabolic and electrolyte abnormalities after chemotherapy for rapidly growing tumors such as Burkitt's lymphoma and leukemias were first published in the 1950s.⁹ Cadman and his colleagues in the 1970s proposed a mechanism that linked these metabolic observations.¹⁰ More recently, TLS has been observed in patients with solid tumors and has been observed in patients receiving immunotherapy, such as IL-2, sunitinib, imatinib, and rituximab.¹¹⁻¹⁴ TLS after treatment for solid tumors is relatively rare.

TLS is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.¹⁰ Electrolyte abnormalities can appear as soon as 6 hours after chemotherapy administration and can persist for 5 to 7 days after treatment. The hyperuricemia comes from the massive release of intracellular nucleic acids and their metabolism by xanthine oxidase into uric acid. Urate crystals can form in the renal collecting ducts and result in oliguric and anuric renal failure. Similarly, potassium and phosphate are released

from lysing tumor cells, and renal excretion of these intracellular ions is impaired by hyperuricemia. Serum calcium levels drop from ectopic calcium deposition; this becomes more likely as the calcium-phosphorus product increases. Calcium deposition is favored by a calcium-phosphorus product greater than $60 \text{ mg}^2/\text{dL}^2$ and becomes severe when the product is more than $75 \text{ mg}^2/\text{dL}^2$. The clinical manifestations of TLS depend on which electrolyte derangement predominates. Tetany, confusion, hypotension, dysrhythmias, and sudden death have been reported with TLS. The most effective management approach for this syndrome is to anticipate its occurrence and intervene prospectively. Patients at greatest risk for TLS are those with a diagnosis of a rapidly growing lymphoma or leukemia with high blast counts, and pretreatment levels of lactate dehydrogenase greater than 1500 U/dL and uric acid greater than 10 mg/dL. Pretreatment azotemia is also a poor prognostic sign. Azotemia may be exacerbated by uric acid nephropathy, which is more common with uric acid levels exceeding 20 mg/dL. It is unlikely that TLS will occur in patients at risk who do not develop metabolic changes within 48 hours after receiving chemotherapy. Guidelines for prophylaxis and treatment of TLS are given in [Box 80.1](#). It is important to note that rasburicase poses an oxidative stress and can induce hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Box 80.1 Tumor Lysis Syndrome: Treatment Recommendations

When no metabolic aberration exists:

- Allopurinol 300 mg/day, reduce to 100 mg/day after 3 days of chemotherapy
- OR
- Rasburicase 0.2 mg/kg IV daily \times 5 days
- Hydration: 0.45% saline 3000 mL/day
- Initiate chemotherapy within 24-48 hours of admission
- Monitor serum chemistry values every 12-24 hours

When metabolic aberration exists:

- Allopurinol OR rasburicase as above; reduce dose if hyperuricemia controlled or for renal insufficiency
- Hydration with D₅W with 2 ampules/L of NaCO₃, add non-thiazide diuretics as needed
- Urinary alkalization to keep urine pH >7.0, may discontinue when serum uric acid level is normal
- Postpone chemotherapy until uric acid decreased and electrolytes stable
- Monitor serum chemistries every 6-8 hours
- Replace calcium with slow intravenous infusion of calcium gluconate (if symptomatic or for ECG changes)
- Treat hyperkalemia and hyperphosphatemia with exchange resins and phosphate binders, respectively

Criteria for hemodialysis in patients unresponsive to the measures listed above:

- Serum potassium >6.0 mEq/L
- Serum uric acid >20 mg/dL
- Serum phosphorus >10 mg/dL
- Fluid overload unresponsive to diuretics

Symptomatic hypercalcemia D₅W, 5% dextrose in water; ECG, electrocardiogram; NaCO₃, sodium carbonate.

HYPERCALCEMIA

Hypercalcemia is the most common metabolic abnormality occurring in cancer patients. Approximately 10% to 20% of all cancer patients have hypercalcemia at some point in their course. The clinical symptoms of hypercalcemia are nonspecific and include lethargy, confusion, nausea, and anorexia. Often the clinical symptoms in cancer patients may be subtle because the onset of hypercalcemia is gradual. The mechanism that underlies all cases of cancer-related hypercalcemia is increased calcium resorption from bone due to enhanced osteoclast activity mediated through receptor activator for nuclear factor κ B ligand (RANKL).¹⁵ This resorption increase can be due to local action of tumor in bone or to the production of bone-resorbing hormones and cytokines by tumor cells remote from bone. Normally, increased circulating calcium results in decreased parathyroid hormone (PTH) production. When PTH levels decrease, bone resorption and renal tubular reabsorption of calcium decline. Low PTH levels cause a decrease in vitamin D production; thus, gut absorption of calcium is lowered. Although PTH levels are suppressed in cancer patients with hypercalcemia, the destructive action of tumor deposits in bone or the action of tumor-produced hormones on bone maintains high calcium resorption rates. This is accomplished through osteoclast activation and proliferation from factors produced by the tumor, such as interleukin 1 (IL-1), tumor necrosis factor (TNF), prostaglandin E₂, granulocyte-macrophage colony-stimulating factor (GM-CSF), transforming growth factor- α , platelet-derived growth factor, and PTH-related peptides.¹⁶⁻²⁰ Malignancies that commonly cause hypercalcemia include multiple myeloma, breast carcinoma, epidermoid lung carcinoma, and renal cell carcinoma. Hypercalcemia in lymphoma and leukemia is probably not associated with PTH-related peptide, but rather with the overproduction of activated vitamin D.^{20,21}

Cardiac complications and renal dysfunction are the most serious end-organ effects of hypercalcemia. Electrocardiogram (ECG) changes include prolongation of the PR and QRS intervals and shortening of the QT interval. Bradydysrhythmias and bundle branch blocks become more frequent with serum calcium levels greater than 16 mg/dL. These may progress to complete heart block and asystole. Renal dysfunction may also occur because increased serum calcium induces a diuretic effect, which can cause moderate to severe dehydration and prerenal azotemia. This process can result in acute tubular necrosis if untreated.

Management for any symptomatic hypercalcemic patient should begin with intravenous hydration, which may increase renal blood flow and enhance calciuresis.²² Renal excretion of calcium can be enhanced with furosemide diuresis, although no randomized trials exist to support its use in hypercalcemia. These measures should be viewed as temporizing steps until definitive treatment has been implemented. The bisphosphonates zoledronic acid, pamidronate, alendronate, etidronate, and clodronate have been shown to be highly effective in the long-term treatment of hypercalcemia of malignancy. These agents work by binding to the hydroxyapatite in bone and preventing calcium resorption, although they may also have much more complicated effects on the cell cycle and bone turnover.^{23,24} A commonly used bisphosphonate regimen is a single dose of

Table 80.1 Agents Used for the Management of Hypercalcemia

Drug	Dosage
Pamidronate	90 mg IV over 2 hours
Zoledronic acid	4 mg IV over 15 minutes
Gallium nitrate	200 mg/m ² by continuous infusion for 5 days
Calcitonin	400 IU SQ every 8 hours
Mithramycin	25 μ g/kg IV once or twice per week

IV, intravenously; SQ, subcutaneously.

pamidronate (60-90 mg intravenously over 2 to 4 hours) or zoledronic acid (4 mg intravenously over 15 minutes). Doses may be repeated in 3 to 4 days if the calcium does not decline. In addition, therapy directed at controlling the tumor should be implemented. RANKL inhibitors are now available for clinical use (denosumab) that inhibit osteoclast activity induced by malignancy and may be more potent in inhibiting bone resorption compared to bisphosphonates.^{25,26} Gallium nitrate can be tried in patients with hypercalcemia unresponsive to bisphosphonates.²⁷ Calcitonin, glucocorticoids, or mithramycin can also be tried in patients unresponsive to first-line therapies, although these therapies are no longer commonly used owing to potential renal injury. Dialysis may be necessary if renal compromise is severe. Treatment recommendations are summarized in Table 80.1.

ONCOGENIC OSTEOMALACIA

Oncogenic osteomalacia is a rare syndrome characterized by severe hypophosphatemia, high serum alkaline phosphatase, aminoaciduria, glycosuria, low levels of 1,25-dihydroxyvitamin D, and normal serum calcium. The syndrome is the result of humoral inhibition of activation of 25-hydroxyvitamin D. Patients present with bone pain and muscle weakness. Hemolysis from hypophosphatemia is a possible sequela of this syndrome. The tumors that give rise to oncogenic osteomalacia are usually vascular mesenchymal tumors, such as hemangiopericytoma. Treatment involves surgical removal of the tumor and phosphate supplementation.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE

SIADH is associated with carcinoid tumors, myeloma, lymphoma, and carcinomas originating in the lung, prostate, esophagus, head and neck, adrenal gland, and pancreas. Cerebral metastasis from any tumor can also give rise to SIADH. Clinical findings are mainly neurologic, often do not correspond precisely to serum sodium levels, and range from mild confusion to coma and seizures. Because the clinical findings are secondary to water intoxication and hyponatremia, treatment involves water restriction (500 mL/day) and control of the primary tumor. More aggressive treatment should be started with 0.9% or 3% saline solution

and furosemide diuresis for patients with neurologic deficits from hyponatremia. The rate of intravenous fluid supplementation should be adjusted based on the urinary excretion of sodium and potassium. Correction of severe hyponatremia (sodium less than 125 mEq/L) should take place over 7 to 10 days. Too rapid a correction can lead to serious neurologic sequelae such as central pontine myelinosis. Patients who fail to respond to water restriction can be treated with demeclocycline (600 to 1200 mg daily), which blocks the peripheral action of antidiuretic hormone (ADH). There is also a new class of selective vasopressin V_2 -receptor antagonists that compete with native vasopressin, resulting in an increase of free water clearance. Tolvaptan (15-60 mg daily) can be used in patients who do not respond to demeclocycline.

ADRENAL FAILURE

Cancers of the lung, breast, kidney, stomach, and pancreas and melanoma are the tumors that metastasize most often to the adrenal glands. It is estimated that more than 90% of adrenal tissue must be destroyed before clinical manifestations of adrenal insufficiency appear. The clinical signs and symptoms of hypoadrenalism include weakness, gastrointestinal complaints, postural hypotension, dehydration, and electrolyte disturbances. The typical electrolyte profile is hyponatremia, hyperkalemia, and a mild anion gap acidosis.

Adrenal failure has also been observed in patients receiving ipilimumab, an antibody that blocks the effects of an inhibitory protein in T cells known as CTLA-4 (cytotoxic T-lymphocyte antigen 4) and is used in the treatment of advanced melanoma.⁴ Hypoadrenalism from ipilimumab is usually secondary to panhypopituitarism induced by T-cell-mediated hypophysitis.²⁸ These patients can present with headache and visual changes from pituitary swelling in addition to the clinical findings of hypoadrenalism as reviewed earlier. Evaluation of these patients should include a contrast-enhanced brain magnetic resonance imaging (MRI), and measurement of serum levels of cortisol, adrenocorticotrophic hormone (ACTH), and thyroid-stimulating hormone (TSH).

The diagnosis of hypoadrenalism can be made with a cosyntropin stimulation test. Plasma cortisol levels are obtained before cosyntropin injection (0.25 mg intravenously) and 30 and 60 minutes after injection. A normal response is an increase in plasma cortisol of at least 7.0 mg/dL in 60 minutes. If the cortisol response to cosyntropin stimulation is suboptimal, physiologic doses of glucocorticoids should be administered twice a day (cortisone acetate, 25 mg every morning and 12.5 mg every evening). Mineralocorticoid supplementation is required in some patients (fludrocortisone, 0.05-0.1 mg daily). If the diagnosis of adrenal insufficiency is highly suspected, treatment should begin immediately after completion of the cosyntropin test. For patients in adrenal crisis with circulatory collapse, hydrocortisone should be given at stress doses (100 mg intravenously every 8 hours). This dose of hydrocortisone should also be adequate to supplement mineralocorticoid-deficient patients. Patients receiving glucocorticoids as part of their chemotherapy regimen (usually lymphoma or myeloma patients) or for treatment of brain tumors

or metastases, may already have adrenal suppression and require stress-dose glucocorticoid replacement during episodes of neutropenic sepsis or elective surgery.

PHEOCHROMOCYTOMA

Pheochromocytoma is most commonly associated with the multiple endocrine neoplasia syndrome. The clinical features of this tumor are related to episodic catecholamine release and include hypertension, severe headache, cardiac dysrhythmias, pallor, perspiration, and rarely, hypotension. Patients can also present with a multisystem crisis characterized by encephalopathy, hyperpyrexia, and hemodynamic instability.²⁹ Diagnosis is made by measuring urinary catecholamine metabolites. An elevated vanillylmandelic acid is accurate approximately 90% of the time in making the diagnosis.³⁰ Patients with borderline catecholamine levels can often be diagnosed with the clonidine suppression test.³¹ Localization of pheochromocytomas can be difficult because the tumors can arise anywhere between the base of the brain and the scrotum and can be multicentric. MRI and computed tomography (CT) are helpful in visualizing adrenal abnormalities. Nuclear medicine studies with m -[¹¹¹I]iodobenzylguanidine (MIBG) can be used if the CT scan is negative. MIBG scans are sensitive and specific for detecting ectopic adrenal medullary tissue.³² Positron emission tomography (PET) imaging and diffusion-weighted MRI can detect sites of disease not apparent on CT or MIBG and can aid in surgical planning.³³⁻³⁵ Surgical extirpation of the tumor is the only effective treatment. Preoperative control of catechol secretion is necessary and can be attained with long- or short-acting α -adrenergic blockade (phenoxybenzamine 10 mg orally two or three times daily or doxazosin 2-16 mg orally daily). A comparison of preoperative management strategies using long- versus short-acting α -antagonists showed no difference in long-term outcome after surgery, although the incidence of intraoperative hypertension was greater with short-acting medications like doxazosin, terazosin, and prazosin.³⁶ Tachycardia can be controlled with beta blockers, but these should be started only after phenoxybenzamine. Patients in hypertensive crisis can be managed with α -methyltyrosine or calcium channel blockers such as nifedipine or nicardipine.³⁷⁻³⁹

TUMOR-INDUCED HYPOGLYCEMIA

Functional endocrine tumors can give rise to a variety of clinical syndromes. Most of these problems can be managed outside the ICU; however, tumor-induced hypoglycemia can cause serious consequences including coma, seizures, and focal neurologic deficits. A number of different mechanisms can give rise to hypoglycemia. Autonomous insulin production is most commonly associated with islet cell tumors, whereas production of insulin-like growth factors (IGF-1 or IGF-2) is seen with non-islet cell tumors.⁴⁰ Slow-growing mesenchymal tumors such as leiomyosarcoma, mesothelioma, and fibrosarcoma are the most common non-islet cell tumors that cause hypoglycemia.

Treatment should be focused on control of the tumor. Insulinomas are often benign and can be cured by surgical removal. For unresectable malignancies, hypoglycemic episodes can often be reduced with supportive measures such

as dietary modification with frequent meals. Insulinomas may respond to diazoxide, an inhibitor of insulin secretion. Glucagon infusions may be beneficial in some patients.⁴¹

CHEMOTHERAPY-INDUCED METABOLIC DISTURBANCES

A number of chemotherapy drugs can cause potentially severe electrolyte disturbances. Cyclophosphamide is associated with hyponatremia from SIADH. Vinca alkaloids such as vinorelbine and vinblastine also cause SIADH. Cisplatin and carboplatin can cause renal tubular defects resulting in hypokalemia and hypomagnesemia, which can be severe enough to require intravenous replacement. Mithramycin lowers serum calcium by a mechanism that is thought to involve inhibition of the effect of PTH on osteoclasts. Although mithramycin can be used for the treatment of hypercalcemia, it can also cause hypocalcemia in patients with normal serum calcium. Cetuximab, a humanized murine antibody directed against the epidermal growth factor receptor (EGFR) and used to treat colon carcinoma and head and neck cancer is associated with severe and symptomatic hypomagnesemia from inappropriate urinary excretion.⁴² Cetuximab may interact with EGFR in the loop of Henle blocking resorption of magnesium and causing secondary hypokalemia and hypocalcemia. Abiraterone, a CYP17 inhibitor of androgen biosynthesis used in men with advanced prostate cancer, also increases adrenal mineralocorticoid synthesis resulting in clinically significant hypokalemia and decreases glucocorticoid synthesis necessitating concurrent administration of prednisone. Everolimus, an oral inhibitor of the mammalian target of rapamycin (mTOR), used in the management of advanced renal cancer and neuroendocrine tumors, can induce severe hyperglycemia requiring insulin.^{43,44} The mechanism through which mTOR inhibitors cause hyperglycemia is not fully understood but may involve decreased insulin secretion, direct toxicity to pancreatic β -cells, or impaired suppression of hepatic glucose production.⁴⁵

CARDIAC COMPLICATIONS IN CANCER PATIENTS

Cardiac dysfunction in cancer patients can be secondary to direct mechanical effects of the tumor on the heart, pericardium, or great vessels. Certain chemotherapy drugs, immunotherapy agents, and radiation can also cause treatment-related cardiac problems. Clinical entities that require emergent and chronic management are discussed.

SUPERIOR VENA CAVA SYNDROME

Obstruction of blood flow through the superior vena cava (SVC) can be caused by fibrosis, thrombosis, external compression, or invasion of the vessel by tumor. SVC syndrome can also be caused by thrombus secondary to a central venous access device, which is now a common fixture of oncologic care. Malignancies that involve the mediastinum, such as lung carcinoma and lymphoma, are the most common causes of this syndrome. Facial and upper extremity edema, facial plethora, headache, and tachypnea are the

most common clinical presentations. Collateral venous channels may be found on the chest or abdomen. Death from SVC syndrome is rare, but life-threatening respiratory compromise and elevated intracranial pressure can occur. Therapy for SVC syndrome depends on the underlying malignancy; thus, a biopsy is mandatory for optimal management of these patients. If lymphoma or small cell lung carcinoma is the cause of SVC syndrome, initiation of the appropriate chemotherapy regimen can rapidly shrink the mediastinal mass and is the treatment of choice. For tumors not responsive to chemotherapy, radiation therapy given with high initial fractions (3 to 4 Gy/day) can provide symptomatic relief in more than 80% of patients.⁴⁶ Thrombolysis has only been studied in catheter-associated SVC syndrome and is effective in this setting.⁴⁷ Endovascular stents can restore patency of the SVC in approximately 50% of patients and can result in significant palliation.⁴⁸ Improvement is often evident within 72 hours and the patency of occluded endovascular stents can sometimes be restored with angioplasty.

CARDIAC TAMPONADE

Although primary or metastatic tumors of the heart can decrease cardiac output by impairing ventricular outflow, the most frequent causes of cardiac tamponade in cancer patients are metastatic tumors of the breast and lung, and melanoma, lymphomas, and leukemias. Tamponade may occur through either encasement of the heart by tumor or production of a malignant pericardial effusion. The clinical manifestations of tamponade include decreased exercise tolerance, shortness of breath, and cough. Voltage may be decreased on ECG with a pulsus alternans pattern present. Muffled heart tones, a pericardial rub, or an increased paradoxical pulse (i.e., decrease in systolic blood pressure on inspiration exceeds 10 mm Hg) may be present on physical examination. Echocardiography is extremely useful in confirming the diagnosis of tamponade if it is suspected on physical examination. Diastolic collapse of the right atrium or right ventricle on echocardiogram is an indicator of hemodynamic compromise.^{49,50} Swan-Ganz catheterization may be helpful to confirm the presence of significant tamponade.

Pericardiocentesis for relief of tamponade is indicated emergently when echocardiographic or clinical evidence of hemodynamic compromise is present. Intravenous infusions of normal saline at high flow rates (100 to 500 mL/hour) may be required to support the patient until a drainage procedure is performed. Although rapid reversal of cardiac filling problems can be accomplished by this procedure, a long-term solution is required. Creation of a pericardial window can prevent the reaccumulation of fluid in more than 90% of patients.⁵¹ Sclerosing agents such as tetracycline and bleomycin have also been used to prevent reaccumulation of pericardial fluid.⁵² Sclerosants may be instilled into the pericardial space after adequate drainage has been accomplished and appear to have a success rate comparable to pericardial window procedures. Some centers also perform pericardial windows using video-assisted thoracoscopy, but there have been no prospective randomized studies showing superior clinical outcomes for subxiphoid versus video-assisted thoracoscopy approaches.⁵³

TREATMENT-INDUCED CARDIAC DYSFUNCTION

A number of chemotherapy medicines have cardiac toxicities that can be life threatening. Cumulative doses of doxorubicin greater than 450 mg/m² are associated with an increased risk for congestive heart failure (CHF). Heart damage from this drug is thought to be from an iron-dependent generation of free radicals, which secondarily cause oxidative damage to lipid membranes and intracellular organelles.⁵² This toxicity can present acutely or months after drug administration. It is more prevalent in older patients and those with a history of coronary artery disease, hypertension, tobacco abuse, or chest radiation therapy. Initial management with diuretics, digoxin, and angiotensin blockers is usually of benefit, but heart failure can be progressive. Liposomal encapsulation of doxorubicin or the use of dexrazoxane to prevent oxygen-derived free radical formation, may diminish the cardiac toxicities of this agent.⁵⁴⁻⁵⁶ Other anthracyclines, such as mitoxantrone and epirubicin, may have a lower incidence of CHF. Furthermore, weekly low-dose boluses or continuous-infusion methods of doxorubicin administration appear to reduce the incidence of clinically significant heart damage. Although anthracycline-induced cardiac damage has generally been considered irreversible, some studies suggest that some improvement in cardiac function may occur with aggressive medical management.⁵⁷ Paclitaxel, which is commonly used in ovarian, breast, and lung carcinomas, is associated with bradydysrhythmias.^{57,58} Ventricular tachycardia, myocardial infarction, and cardiac ischemia have also been reported. Cyclophosphamide, which is commonly used in breast cancer, lymphoma, and stem cell transplant conditioning regimens, is associated with sporadic instances of CHF, which may be severe and occurs within a few days of cyclophosphamide administration, especially at high doses. Hemorrhagic myocarditis with myonecrosis was seen on autopsy specimens from these patients. These events appear unrelated to cumulative dose or method of administration. CHF from ifosfamide has also been reported.⁵⁹ CHF is usually seen approximately 2 weeks after high doses of the drug and appears more frequently in patients with concurrent renal insufficiency. Medical management successfully reverses the heart failure in most patients. CHF is also associated with trastuzumab, an anti-HER2 (human epidermal growth factor receptor 2) antibody used commonly in the management of certain forms of breast carcinoma. The incidence of CHF after trastuzumab in a large randomized trial was between 3% and 4%, and was more common in patients with antecedent cardiac disease, older patients, and those having diminished ejection fraction (EF) after anthracycline-containing chemotherapy.⁶⁰ Most patients with trastuzumab-induced cardiac dysfunction have improved symptoms with appropriate medical management for CHF and discontinuation of trastuzumab.

Serial echocardiography studies have been used to assess cardiac toxicities in patients receiving chemotherapy for many years, but subtle alterations in myocardial function can be missed with standard assessment of EF. A decrease in longitudinal strain assessed by Doppler measurements of tissue velocity at baseline and repeated at 3 months after starting anthracyclines or trastuzumab is a more sensitive predictor of cardiac dysfunction than EF^{61,62} and may be

useful in identifying patients in need of medical management before significant symptoms occur.

Radiation therapy delivered to the chest for the treatment of Hodgkin's disease, lung malignancies, breast cancer, or other neoplasms can result in a number of cardiac toxicities, including radiation pericarditis with tamponade, myocardial fibrosis, and premature coronary artery disease. The toxic effects of radiation therapy are secondary to microvessel fibrosis and may take up to 20 years to appear.⁶³ After mantle-field radiation therapy, the risk of fatal myocardial infarction is more than three times greater than in age-matched control subjects, although mantle-fields are rarely used currently to treat patients with lymphoma. Nevertheless, it is difficult to treat the mediastinum without also treating the heart.

PULMONARY COMPLICATIONS IN CANCER PATIENTS

Many of the same mechanical issues that influence cardiac dysfunction are also pertinent to pulmonary problems with an underlying neoplasm. Chemotherapy and radiation therapy can also cause lasting and sometimes fatal pulmonary complications. Many of these conditions are difficult to diagnose and can be confused with other clinical entities, such as opportunistic infections. Indeed, pneumonias are the most common pulmonary disorder requiring intensive care. A number of acute and chronic pulmonary presentations are discussed.

LYMPHANGITIC TUMOR INVOLVEMENT

Interstitial lung processes in cancer patients may be due to a variety of infectious insults but can also be caused by direct lymphangitic spread of the tumor. The symptoms of lymphangitic involvement are nonspecific and include dyspnea, nonproductive cough, and hypoxemia. Pulmonary hypertension and cor pulmonale can also be present. The diagnosis can be established by video-assisted thoracoscopic biopsy or transbronchial biopsy. Pulmonary microvascular cytologic specimens obtained with a wedged pulmonary artery catheter may be a less invasive way to make the diagnosis of lymphangitic carcinomatosis.⁶⁴ The prognosis of this condition is generally poor, with a life expectancy of 1 to 6 months. Appropriate systemic treatment should be implemented when the site of the primary malignancy is diagnosed.

TREATMENT-INDUCED PULMONARY DYSFUNCTION

A number of chemotherapy agents and radiation therapy can cause pneumonitis leading to chronic pulmonary fibrosis. The chemotherapeutic agents most likely to cause this problem are bleomycin and mitomycin, but other alkylators, nitrosoureas, antimetabolites, gemcitabine, taxanes, and vinca alkaloids can cause pulmonary dysfunction. Inhibitors of the mTOR pathway such as everolimus and temsirolimus used in the treatment of advanced renal cancer can also induce severe pneumonitis.^{44,65} Erlotinib, an inhibitor of the

phosphorylation of EGFR used in the treatment of advanced lung cancer, can also induce severe and irreversible pneumonitis.⁶⁶ The underlying mechanisms for lung injury induced by these agents are not fully understood, but likely involves oxygen-derived free radical toxicity⁶⁷ and dysregulation of leukocyte apoptosis regulated by TNF-receptor family members. TRAIL (TNF-related apoptosis-inducing ligand) has shown promise in preclinical models of bleomycin lung injury and may also have antitumor properties.⁶⁸ We advocate that cancer patients in need of supplemental oxygen should receive the lowest possible fractional concentration of oxygen that produces a hemoglobin oxygen saturation of greater than 90%. Irreversible lung damage can occur if excessive oxygen is administered to patients receiving bleomycin or radiation therapy. Clinical assessment is crucial to patient management because there are no sensitive or accurate tests to predict the onset or course of bleomycin-induced pulmonary toxicity. The resting diffusion capacity has been used, but is suboptimal to follow patients.⁶⁹ Treatment recommendations are based on the recognition of three distinct clinical entities:

1. Patients who have radiographic changes but no symptoms do not require treatment.
2. Glucocorticoids are used for managing pneumonitis induced by chemotherapy, mTOR and EGFR inhibitors, and radiation when fever, cough, shortness of breath, and pulmonary infiltrates are present. The mechanism of glucocorticoid action may involve reducing inflammation and microvessel damage through inhibition of leukotriene synthesis, inducing granulocyte demargination from endothelial cells, and direct toxicity to lymphocytes.
3. There is no effective treatment for patients with chronic pulmonary fibrosis, cor pulmonale, or pulmonary hypertension from chemotherapy or radiation therapy.

DIFFUSE INTERSTITIAL PNEUMONITIS

The differential diagnosis of diffuse pulmonary infiltrates in cancer patients is large. Infectious causes include bacterial, viral, fungal, and protozoal pathogens. Noninfectious causes for diffuse pulmonary infiltrates are neoplasm, autoimmune disease, cardiac failure, leukostasis, pulmonary hemorrhage, and radiation- or chemotherapy-induced pneumonitis. Making a diagnosis on clinical grounds is difficult because the radiographic and physical examination findings are virtually indistinguishable among these diverse causative entities. Performing an open-lung biopsy is often the only way to confirm a diagnosis; however, empiric treatment may result in equally good patient outcomes. A randomized study compared immediate open-lung biopsy followed by therapy directed at the diagnosis versus empiric antibiotics alone without biopsy to treat diffuse pulmonary infiltrates in cancer patients.⁷⁰ The antibiotic regimen included trimethoprim-sulfamethoxazole (20 mg/kg/day intravenously) and erythromycin (30 mg/kg/day intravenously, divided into four daily doses). A broad-spectrum antibiotic was added if the patient was neutropenic at the time of diagnosis. There was no significant difference in the outcome for these patients; however, those who received an open lung biopsy had a greater complication rate. Empiric

antibiotics are appropriate initial management for diffuse interstitial infiltrates, but patients who do not improve after 4 days of empiric therapy should receive open-lung biopsy.

The decision to place a patient with a cancer diagnosis on ventilator support is often controversial for medical staff and families. It is generally recognized that such patients have a poor prognosis, with a mortality rate approaching 80%. A large multicenter trial prospectively examined prognostic variables for cancer patients requiring ventilatory support.⁷¹ Factors having a statistically significant negative influence on survival were a diagnosis of leukemia, allogeneic stem cell transplantation, progressive cancer, cardiac dysrhythmia, presence of disseminated intravascular coagulation (DIC), and need for vasopressor support. Prior surgery with curative intent was protective and probably relates to a selection bias for patients with physiologic reserve sufficient to tolerate surgery. Although this model is similar to other prognostic models used in the ICU setting, it differs in its emphasis on cancer-specific factors. There also appears to be a positive association between recovery from neutropenia, pneumonia, and acute respiratory distress syndrome (ARDS) requiring mechanical ventilation and an inverse relation to survival in patients with hematologic malignancy.⁷² The mortality rate of patients with ARDS during neutropenic recovery was 86.8% versus 51.5% in patients without ARDS in this single institution study. In general, the assessment of the potential reversibility of the organ dysfunction is the critical variable. Most iatrogenic toxicities are reversible, and patients having toxicity from treatment can generally be supported to recovery. Similarly, organ dysfunction from treatable malignancies should be assumed to be reversible. However, when more than three organ systems are failing, the chances of recovery are very small. The decision to place a cancer patient on ventilator support is highly individualized, but such models can assist in counseling families about level-of-care issues.

HEMOPTYSIS

Hemoptysis can be a presenting sign of cancer, especially endobronchial lesions of non-small cell lung cancer. Patients presenting with significant hemoptysis and airway compromise can be palliated with a variety of bronchoscopic techniques including argon or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, photodynamic therapy, stent placement, endoluminal brachytherapy, or combinations of these techniques.⁷³ External beam radiation, pulmonary artery embolization, and blood pressure control can also be effective in controlling hemoptysis.

Bevacizumab, a monoclonal antibody against vascular endothelial growth factor, has been used with chemotherapy agents to increase overall response and time-to-progression in lung cancer. Bevacizumab can also cause significant and life-threatening hemoptysis; especially in patients with squamous cell histologic lung cancer.⁷⁴ The mechanism of hemoptysis after bevacizumab is collapse of the tumor vasculature resulting in tumor cavitation in proximity to major blood vessels. Because cancer outcomes can be improved with bevacizumab, we endorse an aggressive approach in supporting patients who experience hemoptysis as a result of this or other vascular-targeting agents.

INFECTIOUS COMPLICATIONS IN CANCER PATIENTS

Pancytopenia is perhaps the most common sequela of dose-intensive chemotherapy regimens. Fever in the setting of neutropenia in conjunction with bacteremia is a life-threatening complication of many chemotherapy regimens, whether given with adjuvant, palliative, or curative intent. The microbial pathogens that infect neutropenic patients have changed over time. Previously, *Pseudomonas aeruginosa* was one of the most common organisms in this setting, but staphylococci, streptococci, and vancomycin-resistant organisms have become increasingly prevalent.⁷⁵ Improved broad-spectrum antibiotics and hematopoietic growth factors have greatly improved the outcome for febrile neutropenic patients,^{76,77} many of whom can be managed easily without intensive care interventions. This section focuses on septic shock and the infections that commonly occur as complications of cancer treatment. The infections that arise as a consequence of the severe immune compromise after bone marrow transplant are covered separately.

FEBRILE NEUTROPENIA AND SEPTIC SHOCK

Despite appropriate broad-spectrum antibiotics, approximately 10% of febrile neutropenic patients progress to septic shock. Fluid resuscitation and pressor agents such as phenylephrine, dopamine, dobutamine, and norepinephrine remain standard treatment for the hemodynamic consequences of shock despite advances in understanding the physiology and immunologic sequelae of shock and a growing number of drugs that may influence the pathophysiology of this clinical entity. Treatments aimed at modifying the host reaction to sepsis other than hemodynamic support have not been shown to improve outcomes.

NEUROLOGIC COMPLICATIONS IN CANCER PATIENTS

Brain or spinal cord metastases can often be managed outside the ICU but may require acute intervention if there is evidence of increased intracranial pressure or spinal cord compression. Seizure management in the cancer patient also is discussed.

SPINAL CORD COMPRESSION

The tumors that most often cause spinal cord compression from epidural metastases or bony destruction are carcinomas of the lung, breast, and prostate and multiple myeloma. The level of the spinal cord involvement determines the clinical neurologic deficit. Cervical cord compression can cause quadriplegia or respiratory arrest; thoracic, paraplegia, and lumbar involvement can give rise to loss of bladder and bowel function. If the problem is detected when local or radicular pain is the only symptom, treatment with glucocorticoids, radiation therapy using conventional or conformal techniques, or laminectomy can be highly effective. If the patient presents with a neurologic deficit, such as the

inability to walk, the chance of significant improvement is less than 10%.⁷⁸ MRI is the diagnostic test of choice for diagnosing epidural metastases. Glucocorticoids should be started emergently for patients who present with myelopathy (dexamethasone 10 mg followed by 4 mg every 6 hours) and imaging obtained as soon as possible. The maximal effect of dexamethasone on alleviating symptoms may not be achieved at total doses of 24 mg/day. If clinical improvement from glucocorticoids is suboptimal, doubling the dose each day up to a maximum of 200 mg/day total dose may improve symptom control until definitive therapy is implemented.⁷⁹ The standard of care for cord compression had been glucocorticoids and radiation; however, a randomized trial has shown benefit for decompressive surgery followed by radiation.⁸⁰ Eighty-four percent of patients randomized to receive surgery and radiation maintained the ability to walk compared to 57% in the radiation alone group. Better palliation of pain and the duration of ambulation were maintained better in the surgery group. A meta-analysis of 1595 articles describing 2495 patients supports better functional improvement and pain control using surgery with or without postsurgical radiation in the management of malignant spinal cord compression.⁸¹

BRAIN METASTASES AND HEMORRHAGE

Tumor metastatic to the brain may be a localized problem, amenable to surgical resection with good results.⁸² Patients who present with significant peritumoral edema and increased intracranial pressure may suffer brain herniation if acute measures are not taken. Therapy includes high-dose glucocorticoids (dexamethasone 10 mg, followed by 4 mg intravenously every 6 hours), intubation and mechanical hyperventilation to maintain partial pressure of carbon dioxide in arterial blood (Paco₂) between 25 and 30 mm Hg, and mannitol diuresis (1.0 to 1.5 g/kg intravenously as a 20% solution). Patients who do not respond may benefit from higher glucocorticoid doses (dexamethasone 25 to 50 mg every 6 hours). After stabilizing the patient with these acute interventions, definitive radiation therapy or surgery can be started. Prophylactic anticonvulsants are often administered; however, this intervention has scant supportive data and should be held in most patients until a seizure has occurred.^{83,84} Frontal lobe tumor deposits and brain metastases from melanoma are two situations in which prophylactic antiseizure medication should be considered. Newer radiation techniques such as stereotactic or gamma knife radiosurgery can also be effective in controlling or eradicating brain metastatic disease, although this modality is more appropriate for patients with good functional status and a total volume of metastatic disease less than 12 cm³.⁸⁵

Dose-intensive therapy for acute leukemia is associated with prolonged thrombocytopenia and the possibility of intracranial hemorrhage. It was previously thought that such events were highly associated with platelet counts less than 20,000 cells/ μ L⁸⁶; however, the threshold for platelet transfusion used in most medical centers is now 10,000/ μ L, based on a randomized trial that showed no difference in patient outcome with the more stringent threshold.⁸⁷ Other events, such as sepsis and fever, contribute to the likelihood of bleeding with thrombocytopenia. Patients with solid tumors are also less likely than those with leukemia to bleed

as a consequence of thrombocytopenia. In cancer patients with suspected intracranial bleeding and thrombocytopenia, the platelet count should be maintained above 50,000 cells/ μ L. The best strategy to maintain adequate hemostatic function with platelet transfusion support is controversial because platelet kinetics are complex.^{88,89} We advocate frequent dosing or continuous infusion of platelets in actively bleeding thrombocytopenic patients who have poor increments in platelet count after transfusion resulting from platelet sensitization. The blood bank should identify human leukocyte antigen (HLA)-matched platelet donors for such patients and maintain an adequate supply of the HLA-matched platelets. Single-donor platelets are often more effective than pooled platelets in this setting.

UNCONTROLLED SEIZURES

In 15% to 30% of patients who develop brain metastases, the initial sign is a generalized seizure.⁹⁰ Metabolic disturbances, such as hyponatremia from SIADH, may also cause seizures in cancer patients. Acute control can be obtained with intravenous diazepam (5 mg intravenously every 5 to 10 minutes up to 30 mg). Standard measures to protect the airway, prevent aspiration, and avoid limb injury should also be implemented. After acute control has been attained, phenytoin should be started (15 mg/kg intravenously at a maximum rate of 50 mg/minute, then maintenance doses of 300 mg/day). Phenytoin up-regulates the P-450 system in the liver, which may accelerate the metabolism of certain chemotherapy agents, such as paclitaxel and docetaxel.^{91,92} Levetiracetam (1000 mg daily) is also highly effective in the acute and chronic management of seizures induced by brain malignancy.⁹³ Antiseizure agents that do not influence P-450 cytochromes, like gabapentin, should be used in patients requiring taxane-based chemotherapy. Serum levels of phenytoin and levetiracetam should be monitored.

Seizures, coma, and other neurologic complications can occur with a variety of chemotherapeutic and biologic agents. Most of these toxicities improve with cessation of the causative agent and supportive care. Ifosfamide-induced neurotoxicity has a unique mechanism related to changes in mitochondrial fatty acid oxidation and the accumulation of glutaric acid metabolites.⁹⁴ Treatment with methylene blue (200-300 mg orally or intravenously daily), an electron-accepting drug, can reverse and prevent neurologic toxicity during ifosfamide infusion.⁹⁵

GASTROINTESTINAL COMPLICATIONS IN CANCER PATIENTS

Bowel injury is a common cause of morbidity and death in cancer patients. Lymphomatous bowel involvement is relatively common in acquired immunodeficiency syndrome (AIDS)-lymphoma patients⁹⁶ and can be a site of metastatic disease in a variety of solid tumors including ovarian cancer, melanoma, and renal cancer. Management of these problems can often be accomplished with meticulous standard care; however, intensive support may be needed for emergent surgical or medical conditions arising from gastrointestinal complications.

TUMOR-INDUCED EMERGENCIES

For most tumor types, obstruction may be related to a localized lesion that is readily amenable to surgical correction. In women with ovarian cancer, the obstruction is often related to loss of peristalsis in long segments of bowel because of diffuse wall invasion by malignancy. Little can be done with surgical intervention in such circumstances. Improvement hinges on the availability of effective chemotherapy. Bowel obstruction or perforation can occur from primary or metastatic tumors. If the patient presents with peritoneal signs of an acute abdomen, then emergent exploratory surgery is indicated.⁹⁷ For less clear-cut presentations, abdominal radiographs, CT scans, and endoscopy may be helpful. These patients can be managed initially with bowel rest, nasogastric suction, and anaerobic antibiotic coverage until a diagnosis is made. Somatostatin can provide palliation in some patients, probably by increasing intestinal water resorption.⁹⁸

Biliary obstruction can occur from primary tumors of the pancreas, bile ducts, or gallbladder but more commonly is from tumors metastatic to the porta hepatis, such as breast carcinoma, melanoma, or lymphoma. Ascending cholangitis and sepsis are possible sequelae if bile drainage is not accomplished. A percutaneous or endoscopic approach can be used to decompress the bile ducts emergently. Effective treatment of the primary tumor should be implemented when possible. If the tumor is unlikely to respond to chemotherapy or radiation therapy, palliation with an internal stent or an operative biliary diversion procedure is indicated.

Hemorrhage of an abdominal viscus can occur from chemotherapy or progressing tumor. Identifying the source of the bleeding can be accomplished with endoscopy, CT scan, angiography, or labeled red blood cell studies. Bleeding from ulcers or mucosal irritation from chemotherapy can usually be managed medically or with endoscopic control via heater probe or Nd:YAG laser. If a tumor deposit is the cause, surgical control of the site should be considered. If the patient is not a surgical candidate, an angiographic embolization procedure may provide effective palliation.

CHEMOTHERAPY-INDUCED GASTROINTESTINAL DYSFUNCTION

Typhlitis (ileocecal syndrome) is seen most often in patients with leukemia receiving induction chemotherapy. It presents usually after more than 7 days of neutropenia with watery diarrhea, abdominal distention, and right-sided abdominal tenderness. Bowel rest and antibiotics may be successful in treating this condition, but surgery is required for repeated sepsis, bowel necrosis, or perforation. This syndrome can occur on subsequent cycles of chemotherapy; thus, a colonic diversion procedure may be needed in order to complete chemotherapy.

Colitis can occur in up to 40% of patients who have received ipilimumab of whom 5% experience severe symptoms including high-output diarrhea and intestinal perforation.^{4,99} Neutrophilic and lymphocytic infiltrates are evident on biopsy consistent with the idea that ipilimumab elicits autoimmune tissue damage by breaking

self-tolerance. Intervention early when symptoms are mild or moderate (e.g., 4-6 stools per day over baseline) is key to avoiding severe or life-threatening colitis. Initial management is to withhold ipilimumab and administer loperamide. If symptoms persist, then a course of glucocorticoids should be started (e.g., prednisone 0.5 mg/kg/day). For patients who have seven or more stools per day, abdominal pain, melena, or hematochezia, then glucocorticoids (e.g., prednisone 1-2 mg/kg/day) should begin promptly with a slow taper when symptoms resolve. Endoscopic evaluation may be helpful. Emergent surgery for perforation is appropriate. TNF inhibitors (e.g., infliximab) can be effective in managing diarrhea from ipilimumab unresponsive to glucocorticoids.⁹⁹ Figure 80.1A and B depicts the biopsy findings in ipilimumab colitis and an associated tumor response.

A number of chemotherapy agents can decrease bowel motility resulting in ileus. Examples of such medications are paclitaxel, vincristine, and cytosine arabinoside. Supportive care of the ileus is usually successful, but toxic megacolon can occur and is an indication for surgical management.

A particularly difficult management problem is the severe constipation that can accompany the use of opioid analgesics in patients with advanced cancer. Prophylactic measures are very important, including the use of stool softeners and osmotic laxatives and maintaining patient activity as much as possible. Even with optimal prophylaxis, results are often unsatisfactory. Methylnaltrexone, a μ -opioid receptor antagonist that does not cross the blood-brain barrier, can significantly improve constipation, usually within 4 hours of dosing, without reducing the analgesic effect of narcotics.¹⁰⁰

Figure 80.1 Ipilimumab enterocolitis and treatment response. **A**, Photomicrograph of a biopsy (hematoxylin and eosin stain, $\times 100$) from the descending colon of a patient with severe diarrhea after ipilimumab immunotherapy. Extensive neutrophilic infiltration of colonic crypts is present (arrows), which is a hallmark of ipilimumab enterocolitis. **B**, Before (left) and after (right) positron emission tomography computed tomography images on the same patient. The large fluorodeoxyglucose (FDG)-avid chest wall melanoma mass (arrows) has a standard uptake value (SUV) of 46 that has regressed significantly in size and shows normal FDG uptake (SUV < 2) after ipilimumab.

GASTROINTESTINAL LYMPHOMAS

Lymphoma presenting as a gastric or intestinal mass is common in AIDS patients and in patients with B-cell lymphomas arising in mucosal-associated lymphatic tissue (MALT) secondary to *Helicobacter pylori* infection. This situation warrants extreme caution because perforation of an abdominal viscus is a potentially life-threatening complication of potentially curative chemotherapy. Because perforation is a major concern in these patients, initial surgical resection is advocated by some authors.^{101,102} Others have noted low rates of abdominal catastrophe in patients treated with chemotherapy and radiation therapy alone.¹⁰³ Data from patients with gastric MALT lymphoma treated with antibiotics or radiation therapy suggest that perforation is rare in patients achieving a tumor response.¹⁰⁴ Patients with extensive gastric involvement by lymphoma should start chemotherapy in the hospital with surgical consultation to monitor for possible perforation or obstruction. Perforation is more common in patients with small intestinal involvement with aggressive histologic lymphomas compared to gastric or colon involvement by lymphoma.

GENITOURINARY COMPLICATIONS IN CANCER PATIENTS

Intensive care interventions for genitourinary tract problems may be required for the sequelae of obstruction or primary renal dysfunction. Tumors arising locally, metastatic tumors, and certain chemotherapy drugs can give rise to genitourinary problems. Both tumor-induced and chemotherapy toxicities are discussed.

TUMOR-INDUCED GENITOURINARY DYSFUNCTION

Obstructive uropathy resulting in hydronephrosis can occur at the bladder outlet or anywhere along the path of the ureter. Bladder outlet problems are most commonly caused by local tumor invasion from prostate, bladder, rectosigmoid, cervical, or ovarian neoplasms. Metastatic deposits from gastric, breast, or pancreatic malignancies can also obstruct the bladder outlet. Tumors that arise from retroperitoneal structures or metastasize to the retroperitoneum can cause ureteral obstruction. Examples of tumors that commonly have a retroperitoneal presentation are Hodgkin's and non-Hodgkin's lymphoma, germ cell tumors that metastasize to retroperitoneal lymph nodes, and axial sarcomas. Primary tumors of the ureter can also cause obstruction. If the obstruction and the resulting hydronephrosis are of short duration, percutaneous drainage and decompression are recommended. If there is a concurrent infection, decompression is mandatory and constitutes an oncologic emergency. After a period of 48 to 72 hours, a ureteral stent can be placed using the antegrade or retrograde approach. Furosemide-renal scanning can be used to confirm the presence of kidney function if there is a question about the reversibility of the functional impairment of the obstructed kidney.¹⁰⁵ After stenting, appropriate radiation therapy, chemotherapy, or hormonal treatment should be implemented for control of the malignancy.

Renal function can also be compromised indirectly by malignancies. The nephrotic syndrome is seen in association with several solid tumors, such as colon, gastric, ovarian, and breast carcinomas. Lymphomas, especially those of T-cell origin, and chronic lymphocytic leukemia can also cause nephrotic syndrome and other glomerulopathies. Multiple myeloma and Waldenström's macroglobulinemia can produce amyloid and cryoglobulin deposits in the kidneys, resulting in acute tubular necrosis or interstitial nephritis. Recurrent and chronic pyelonephritis is common in patients with myeloma. Dialysis may be necessary to support the patient until effective antitumor therapy is given.

CHEMOTHERAPY-INDUCED GENITOURINARY COMPLICATIONS

Hemorrhagic cystitis can be caused by acrolein, a metabolite of cyclophosphamide and ifosfamide. This problem can usually be prevented with adequate hydration, bladder irrigation, or the use of thiol-based chemoprotectants, such as mesna. Mesna administration is mandatory for ifosfamide treatment. If the hemorrhagic cystitis is severe and unresponsive to supportive measures and saline bladder irrigation, formalin bladder instillation can be performed under general anesthesia.¹⁰⁶ A 1% formalin solution should be used, but bladder fibrosis and strictures may occur despite this low concentration. Care must be taken to avoid reflux of the formalin up the ureters. Urinary diversion and cystectomy may be required for uncontrolled bleeding.

Methotrexate, an antifolate chemotherapy agent, can precipitate in renal tubules and cause acute tubular necrosis if adequate hydration and urinary alkalization are not achieved before therapy. If renal toxicity occurs, leucovorin rescue should be started, based on serum levels of methotrexate (Table 80.2 provides details of methotrexate toxicity prevention or reversal). Intravenous fluids containing bicarbonate, furosemide, and mannitol may be helpful in preventing oliguric renal failure.

HEMATOLOGIC COMPLICATIONS IN CANCER PATIENTS

Although clinical prodromes for leukemias may evolve over weeks or months, treatment for these disorders, once

Table 80.2 Leucovorin Rescue for Methotrexate Toxicity

Methotrexate drug levels above 5×10^{-7} at 48 hours after infusion require additional leucovorin rescue as follows:

Drug Level	Leucovorin Dosage
5×10^{-7}	15 mg/m ² q6h × 8 doses
1×10^{-6}	100 mg/m ² q6h × 8 doses
2×10^{-6}	200 mg/m ² q6h × 8 doses

Drug levels should be measured every 24 hours and leucovorin dose adjusted until drug concentration is less than 5×10^{-8} .

diagnosed, is often urgent and requires intensive care support. This support is needed not only to treat a number of well-known disease-related complications, but also to manage chemotherapy toxicities because some of the most dose-intensive drug regimens are used against these malignancies.

HYPERLEUKOCYTOSIS

Large numbers of leukemic blasts may be present in acute leukemias or in the late stages of chronic leukemias. When the number of circulating myeloblasts is greater than 100,000 cells/ μ L, the viscosity of the blood increases because white blood cells are much less deformable than red blood cells. Patients with chronic lymphocytic leukemia can tolerate higher circulating numbers of malignant cells (e.g., 100,000-300,000 cells/ μ L) without consequence. In acute leukemia, the blasts may invade and weaken the vessel wall, leading to hemorrhage. Hyperleukocytosis chiefly affects the microvasculature in the lungs and the central nervous system. Symptoms can range from mild shortness of breath and blurred vision to pulmonary congestion, hypoxia, intracranial hemorrhage, and TLS (tumor lysis syndrome). Rapid institution of leukapheresis can often decrease leukocyte counts by 20% to 50%.¹⁰⁷ Although the improvement may be transient, chemotherapy treatments for the underlying leukemia can be accomplished with greater safety, and perhaps a lesser degree of TLS.

All-*trans*-retinoic acid (ATRA), used in the treatment of acute promyelocytic leukemia (APL), induces differentiation of leukemic cells.¹⁰⁸ ATRA is associated with a leukocytosis syndrome characterized by fever, dyspnea, and interstitial lung infiltrates on chest radiograph, which can progress to ARDS.¹⁰⁹ ARDS may be secondary to accumulation of differentiated leukemic blasts and their release of cytokines, such as IL-2, in the lung. Leukapheresis is ineffective in this setting; however, the early implementation of glucocorticoids is beneficial (dexamethasone 10-20 mg/day in divided doses).

DISSEMINATED INTRAVASCULAR COAGULATION

DIC can be associated with a variety of solid tumors, including carcinoma of the prostate, lung, breast, and gastrointestinal tract, and melanomas. However, DIC is the hallmark of the clinical presentation for APL. The leukemic blasts in APL manufacture procoagulants, which are released into the circulation, particularly after cytotoxic chemotherapy.¹¹⁰ The use of ATRA for treating APL has lessened the severity of DIC in this illness, but a new complication has been added (discussed in the previous paragraph). To manage DIC in APL, serial determinations of fibrin split products and fibrinogen levels should be made. Replacement of fibrinogen can be accomplished with cryoprecipitate (1 bag/2 kg of body weight initially, followed by 1 bag/10-15 kg of body weight daily). If DIC worsens after cryoprecipitate, intravenous heparin can be started but should be used cautiously. Antifibrinolytic agents, such as epsilon-aminocaproic acid, should be avoided because they can block the normal dissolution of thrombi and increase organ damage.

The most effective approach to DIC is prevention. Given the reciprocal serious complications associated with using

ATRA alone or cytotoxic chemotherapy in the treatment of APL, the DIC and ATRA syndromes are best prevented by using ATRA and combination chemotherapy together so that the mass of cells differentiating in response to ATRA can be reduced to levels by the cytotoxic chemotherapy that do not result in sticking and sludging in the lungs.

BIOLOGIC THERAPY

Advances in molecular biology have made large quantities of cytokines, monoclonal antibodies, and chimeric molecules available for clinical use and testing. Examples of biologically active compounds that have been approved for patient use or are in clinical trials include the interferons (α , β , and γ), interleukins (IL-2, IL-7, IL-15, IL-21), colony-stimulating factors (GM-CSF), monoclonal antibodies (anti-HER2 [trastuzumab, Herceptin], anti-CD20 [rituximab, Rituxan]), T-cell directed antibodies (ipilimumab, anti-PD-1, anti-41BB, anti-OX40), and antibody-radioisotope conjugates (tositumomab [Bexxar]). Intensive basic science and clinical research efforts are ongoing to realize the full potential of these molecules and to understand toxicities, which can be severe and require ICU management. IL-2, which is used to treat metastatic melanoma and renal cancer, is the biologic therapy most likely to induce toxicities requiring ICU management. T-cell-directed antibodies such as ipilimumab are gaining wider use and also have the potential to induce severe toxicity.

INTERLEUKIN 2

IL-2-induced capillary leak is the chief underlying cause for most of its end-organ toxicity. The capillary leak is associated with endothelial relaxation caused by nitric oxide.^{111,112} Clinical data also support the notion that nitrate levels are greatly elevated in patients treated with IL-2.¹¹³ In addition, the adhesion of activated lymphocytes to vascular endothelium after IL-2 administration has been shown to cause vascular leak in a rabbit model.¹¹⁴

The most common serious manifestation of IL-2-induced capillary leak is hypotension with essentially the same hemodynamic findings of warm shock¹¹⁵; thus, effective support for these patients requires the use of parenteral α -adrenergic agonists, such as phenylephrine or dopamine.^{116,117} Recommendations for treating cytokine-induced hypotension are given in Table 80.3. Fluid administration, though of transient benefit, often exacerbates the pulmonary capillary leak seen with IL-2. IL-2 infusions can be continued, despite hypotension, with appropriate pressor management. In our clinical experience, phenylephrine doses of up to 500 μ g/minute can be tolerated to reverse IL-2-induced hypotension in this selected group of patients who have normal cardiopulmonary function before treatment. IL-2 doses are held until capillary leak has improved sufficiently to warrant a decrease in phenylephrine to less than 100 μ g/minute and can be resumed thereafter in the absence of other dose-limiting toxicities.

INTERLEUKIN 2 PULMONARY CAPILLARY LEAK

The clinical manifestations of IL-2 pulmonary toxicity often do not correlate with the severity of radiologic findings.

Table 80.3 Schema for the Treatment of Cytokine-Induced Hypotension

Blood Pressure (BP) (mm Hg)	Treatment
80 < BP < 90 (asymptomatic)	500 mL 0.9% saline bolus followed by intravenous infusion at 150 mL/hr Phenylephrine 50 µg/min IV titrated up to 200 µg/min to maintain systolic BP >90
70 < BP < 80	Maintain or consider increase in phenylephrine dose and add dopamine; titrate to maximum of 20 µg/kg/min to maintain systolic BP >90
BP < 70 or 70 < BP < 80 on maximal phenylephrine dose	Consider: norepinephrine infusion, methylprednisolone
BP unresponsive to above, or cardiac sequelae of hypotension	Hetastarch 250 mg IV bolus q6, methylene blue 1-3 mg/kg IV over 5 min, followed by infusion at same rate if bolus increases BP

Between 70% and 80% of patients receiving IL-2 have some radiographic abnormality, which may consist of pleural effusions, diffuse infiltrates, or focal infiltrates.^{118,119}

Because clinically significant pulmonary capillary leak cannot be anticipated by radiographic findings, relatively minor symptoms such as tachypnea need to be carefully evaluated in patients receiving IL-2. Pulse oximetry is sometimes helpful but can be falsely low in patients concurrently receiving phenylephrine for IL-2-induced hypotension; therefore, an arterial blood gas may be required for these patients. Hypoxemia should be treated with oxygen supplementation, which can be delivered initially via nasal cannula, Venturi mask, or positive-pressure airway ventilation. Worsening hypoxemia may sometimes respond to diuresis; however, intubation may be required in some patients. A key to the ventilatory management of IL-2 lung toxicity is to reverse the pulmonary edema through positive end-expiratory pressure and enhancement of renal function. Although high partial pressures of oxygen may be required in the initial treatment of these patients, prolonged oxygen exposure may exacerbate IL-2 toxicity.¹¹⁶ For this reason, rapid titration of oxygen to maintain arterial partial pressure oxygen greater than or equal to 60 mm Hg is recommended. If diffuse pulmonary infiltrates worsen and an ARDS-like syndrome develops, parenteral glucocorticoids should be administered. The beneficial effect of glucocorticoids may be mediated by the lysis of activated lymphocytes that have been stimulated by IL-2.¹²⁰

INTERLEUKIN 2 RENAL DYSFUNCTION

Hypotension and the systemic capillary leak associated with IL-2 also create renal and liver toxicities. The renal dysfunction typically consists of oliguria and prerenal azotemia with elevated blood urea nitrogen and creatinine.^{121,122} Creatinine levels greater than 6.0 mg/dL or 530 µmol/L are often

tolerated without modifying IL-2 doses because recovery is rapid after IL-2 treatment is completed without hemodialysis. The associated oliguria mandates meticulous fluid management because pulmonary toxicity may be exacerbated by fluid overload. Furosemide, or other nonthiazide diuretics, can be tried but are infrequently effective and may exacerbate IL-2-related hypotension.

CARDIAC RHYTHM DISTURBANCES AND MYOCARDIAL INFARCTION

IL-2 is associated with a variety of cardiac problems, including nonspecific ST-segment or T-wave changes, dysrhythmias (most commonly supraventricular tachycardia, but ventricular tachycardia can also occur), myocarditis, pericarditis, and myocardial ischemia or infarction. The rhythm disturbances and inflammatory conditions may be secondary to lymphocyte infiltration of the myocardium or pericardium.¹²³ Cardiac toxicity (with the exception of sinus tachycardia) should be treated initially by holding or discontinuing IL-2 doses. Supraventricular tachycardia may respond to adenosine (12 mg by rapid intravenous bolus) and is our agent of choice when IL-2-induced hypotension is present. If hypotension is present and adenosine is ineffective, intravenous diltiazem at doses between 0.15 and 0.45 mg/kg should be considered (as long as the QRS complex is not prolonged, >0.12 second) because the incidence of hypotension appears to be less than with other calcium channel blockers.¹²⁴ Amiodarone is useful in treating atrial fibrillation that occurs in approximately 5% of patients receiving IL-2. After sinus rhythm is reestablished, amiodarone can be continued (200-400 mg orally daily) to prevent or lessen the incidence of atrial fibrillation and IL-2 can generally be continued. Other cardiovascular events should be managed with the same medical and intensive care interventions used for any other acute cardiac patient.

ALLERGIC AND ANAPHYLACTIC REACTIONS TO MONOCLONAL ANTIBODIES

Allergic reactions to monoclonal antibodies occur in 10% to 15% of patients, probably because some agents are chimeric mouse proteins. However, even humanized antibodies can produce shortness of breath, tachycardia, and hypotension, especially with the first infusion. The symptoms may result from complement activation by the antibody and can often be safely managed by slowing or temporarily stopping the antibody infusion. When symptoms abate, the antibody infusion can be resumed at half the initial rate. Mild allergic manifestations, such as urticaria and pruritus, can be managed with oral antihistamines. We advocate a stepwise approach, starting with H₁ blockers (diphenhydramine, 50 mg every 4 hours alternating with hydroxyzine, 50 mg). H₂ blockers (ranitidine 150 mg every 12 hours) may be added if urticaria worsens. Pharyngeal and laryngeal edema can occur, with or without bronchospasm. Clinical manifestations of upper airway edema include drooling, phonation changes, and a sensation of throat pain or tightness. For these more severe presentations, stopping the antibody and a period of observation in the ICU setting is recommended. Parenteral antihistamines should be started, along with inhaled β₁-agonists if bronchospasm is present. Fiberoptic endoscopic examination of the

hypopharynx should be performed to determine the extent of the edema. If repeat fiberoptic examination after 4 to 6 hours shows resolution of the edema, resumption of the antibody at the lower dose or reduced flow rate can be considered. If laryngeal edema worsens, intubation may be necessary to protect the airway.

There are rare patients who experience an anaphylactic reaction with circulatory collapse after monoclonal antibody treatment or other immunotherapy. This response is not always predicted by test doses of the antibody. The prognosis for these individuals in our clinical experience is poor, with a mortality rate approaching 100% despite the prompt implementation of intensive care support.

IMMUNE-MEDIATED TOXICITIES FROM T-CELL-DIRECTED THERAPY

A new class of monoclonal antibodies directed at the regulatory pathways of T cells is being developed, and has shown great promise in inducing durable antitumor effects in a variety of solid tumors, myeloma, and leukemia. The four T-cell pathways under investigation are CTLA-4, PD-1, OX40, and 41BB. Thus far, ipilimumab, a monoclonal antibody antagonizing the inhibitory function of CTLA-4, is the only one of these T-cell-targeted antibodies that has been approved by the Food and Drug Administration (FDA) for the treatment of advanced melanoma, but it is likely that more T-cell-directed agents will enter oncologic practice in the future.

The toxicities of ipilimumab have been extensively reviewed¹²⁵ and include rash, diarrhea, colitis with perforation, endocrinopathies, hepatocellular injury, fatigue, and pyrexia. The toxicities are presumed due to T-cell activation induced by CTLA-4 blockade by ipilimumab, although the precise mechanism is not well understood. Of these toxicities, immune-mediated colitis has the greatest potential to induce critical illness, as discussed earlier.

SPECIAL CONSIDERATIONS IN BONE MARROW TRANSPLANTATION

High-dose chemotherapy with stem cell support is central to managing many leukemias, myeloma, and lymphoma. It has been used in other illnesses including collagen vascular diseases and aplastic anemia. A number of life-threatening toxicities are unique to this form of dose-intensive therapy and require intensive care management. The pathophysiology and treatment recommendations for these entities are discussed later.

ACUTE AND CHRONIC GRAFT-VERSUS-HOST DISEASE

Graft-versus-host (GVH) disease is most commonly seen in the setting of allogeneic transplants but can be observed after syngeneic and autologous transplants. It is well documented that GVH disease can reduce recurrence rates in leukemia¹²⁶; it also lowers overall survival after transplant. The prerequisites for GVH disease are that the graft must include a population of immunologically competent T cells, the graft recipient must be unable to destroy these cells, and

tissue antigens must be present in the recipient that are not present in the donor.¹²⁷ Studies of the immunobiology of GVH disease suggest that dysregulation of T-cell subsets (CD4⁺, CD25⁺, Foxp3⁺, Treg, and T_H17) are instrumental in the clinical manifestations of GVH disease and represent potential therapeutic targets.^{128,129}

The clinical manifestations of GVH include skin rash (maculopapular or diffusely erythematous), liver function abnormalities, and gastrointestinal symptoms including diarrhea, nausea, vomiting, and ileus.¹²⁶ These toxicities are graded (I to IV) on a semiquantitative basis. Grade I or II GVH disease has relatively little morbidity, but grade IV GVH disease carries a 100% mortality rate. Treatment of established GVH disease requires suppression of the immune system. The drugs used most commonly to suppress GVH disease are glucocorticoids, cyclosporine, tacrolimus, and methotrexate, which are usually used in combination. Gamma globulin infusions may also be beneficial in the prophylaxis of GVH disease.¹³⁰ The mechanism of action of gamma globulin is unknown but may involve binding to Fc receptors, which may prevent T cells from recognizing target tissues.

VENO-OCCLUSIVE DISEASE

Hepatic veno-occlusive disease (VOD) is a clinical syndrome characterized by weight gain (fluid), tender hepatomegaly, and elevations of hepatocellular enzymes and bilirubin. The syndrome is the result of endothelial toxicity from high-dose chemotherapy, and results in a local hypercoagulable state with tissue factor synthesis, down-regulation of thrombomodulin, and release of von Willebrand factor with the resultant formation of blood clots in hepatic veins.¹³¹ The incidence of VOD has diminished with the prophylactic use of heparin.¹³² Agents used in the treatment of established VOD include tissue plasminogen activator,¹³³ antithrombin III,¹³⁴ antioxidant therapy,¹³⁵ and transjugular intrahepatic portosystemic stent-shunt.¹³⁶ Clinical trials using a polydisperse oligonucleotide known as defibrotide¹³⁷ are showing activity and defibrotide may be helpful in both the prevention and treatment of VOD. Intensive support is often needed for patients with VOD. Despite aggressive treatment, the mortality rate for severe established VOD approaches 100%.¹³⁸ Patients with milder disease may recover with supportive measures. Early recognition and intervention are key factors influencing outcome.

INFECTIOUS COMPLICATIONS OF STEM CELL TRANSPLANTATION

Different facets of immune function return at varying intervals after bone marrow transplant.¹³⁹ Integumentary and mucosal barriers are disrupted in the period immediately after myeloablative chemotherapy. For this reason, aerobic bacteria and *Candida* organisms are the most likely pathogens early after transplant. There are decreased neutrophil numbers for the first 2 to 4 weeks after transplant, although the use of colony-stimulating factors shortens the neutrophil recovery period. Until neutrophil numbers increase, herpes simplex virus, *Candida*, *Aspergillus*, and bacterial infections are common. It should be noted that the full chemotactic function of neutrophils does not return for 100

days after transplant. Cellular and humoral immunity defects persist for 1 to 3 months after transplant and may lengthen if GVH disease occurs. Fungal and cytomegalovirus (CMV) infections predominate in this period.^{140,141} From 3 months to 1 year after transplant, T cells remain dysfunctional and disordered immunoregulation may occur. Varicella zoster, hepatitis C, *Pneumocystis jiroveci* pneumonia, and pneumococcal pneumonia are the most common infections until T-cell function has recovered. Immune deficits may be moderated by antigen-specific immunity conferred by the transplanted marrow and the use of gamma globulin infusions, which are now routinely given after allogeneic transplant. Antibiotic recommendations in bone marrow transplant are similar to those for other febrile neutropenic cancer patients. Individual recommendations should take into account the frequency of specific microorganisms isolated at a given institution. Trimethoprim-sulfamethoxazole and fluoroquinolone antibiotics (e.g., ciprofloxacin) are routinely used for the prophylaxis of *Pneumocystis* organisms and gram-positive infections, respectively. Invasive fungal infections can be a significant cause of morbidity and death after transplant, but voriconazole prophylaxis or secondary therapy can be effective. CMV responds poorly to single-agent therapy, but the combination of ganciclovir and gamma globulin infusions improves outcome in these patients. Death rates from CMV pneumonitis approached 80% before use of the combination regimen. The use of CMV-negative donors and the elimination of CMV-contaminated leukocytes from platelet and red blood cell transfusions with leukocyte filters have reduced the mortality rate from CMV infection.

There has been ongoing work in using cytotoxic T-lymphocyte (CTL) clones to treat specific opportunistic infections including those from CMV, Epstein-Barr virus (EBV), and adenovirus.¹⁴²⁻¹⁴⁴ Augmentation of antiviral activity was conferred with these infusions in most patients.¹⁴⁵ This strategy may prove useful in reducing the number of life-threatening infections in bone marrow transplant, human immunodeficiency virus, and other immunodeficiency states.¹⁴²

CODE STATUS AND INTENSIVE CARE IN CANCER PATIENTS

The high cost of intensive care and the demands placed on these precious resources by all medical and surgical subspecialties mandate that critical care interventions be meted out wisely. Because cost containment has become imperative in medicine practice and health care reform, certain poor prognosis illnesses, including cancer, are perceived by the public and often by medical staff as relative contraindications to cardiopulmonary resuscitation (CPR) or intensive care interventions.¹⁴⁶ Although several studies have shown that CPR in patients with cancer diagnoses has a low success rate (less than 10%),^{147,148} the success rate of CPR in non-cancer diagnoses is less than 5%.¹⁴⁹ Hospital utilization studies do not support the notion that a disproportionate amount of special care resources are used in terminally ill cancer patients.¹⁵⁰ The central determination in each case should hinge on the answer to a single question: "Is it likely that these abnormalities are reversible?" For nearly all

iatrogenic toxicities, the answer is generally yes. For patients with curable tumor types, every effort should be made to support the patient until the long-term prognosis of the underlying tumor can be ascertained. Given that nearly 60% of individuals with a cancer diagnosis are cured of their disease, intensive care interventions are justified.

When viewed in the context of other underlying medical conditions, a cancer diagnosis is neither medically nor ethically a contraindication to intensive care management. The wishes of the individual and the family are central in establishing an appropriate level of care for any patient. In order to better define the level of care desired by individuals with serious or terminal illnesses, the state of Oregon originated a program known as POLST (Physician Orders for Life-Sustaining Treatment), which is now being implemented in at least 15 other states.¹⁵¹ In cancer patients, the compliance of physicians with documented care preferences is generally greater than 90%, but the timing and extent of this documentation vary.¹⁵² Public awareness of these issues is increasing, and many cancer patients now have such directives, which include living wills, do-not-resuscitate orders, and POLST. These directives can be helpful to the physician and the patient's family, although they sometimes complicate medical management in clinical situations in which reversible conditions exist but for which care might require violating a directive.¹⁵³ Patient education and strong support from social work and pastoral and legal services can assist the physician in arriving at the appropriate level of care for each individual.

SUMMARY

Intensive care support can be a critical component of the success of any dose-intense cancer treatment modality. Support of treatment toxicities is justified given the growing improvement in outcome for cancer diagnoses. Understanding of the pathophysiology of a number of clinical entities, such as septic shock and cytokine-induced hypotension, will provide the basis for more rational and effective management of many of these toxicities. However, it is even more important to develop cancer treatments that attack the malignancy and spare the host. This level of therapeutic sophistication is attainable through our increasing knowledge of the molecular basis of malignancy and the physiology of tumors. Even when the goal of therapeutic specificity in oncology is achieved, intensive care will still be salient in the support of patients presenting with the end-organ sequelae of malignancy.

KEY POINTS

- TLS occurs most frequently in rapidly growing lymphomas or leukemias with high myeloblast or lymphoblast counts. The most effective management strategy is to anticipate the occurrence of TLS and initiate allopurinol, hydration, and intensive monitoring before metabolic aberrations occur.

KEY POINTS (Continued)

- Hypercalcemia is the most common metabolic disturbance in cancer patients. Intravenous hydration and bisphosphonates are the initial treatments for hypercalcemia.
- SIADH in cancer patients often presents with neurologic findings. The initial treatment is fluid restriction.
- Treatment of SVC syndrome depends on the underlying histologic diagnosis; therefore, a biopsy is mandatory in previously undiagnosed patients. If SVC is secondary to lymphoma or small cell lung cancer, chemotherapy is the treatment of choice. Radiation with high initial dose fractions can be palliative in more than 80% of patients with malignancies unresponsive to chemotherapy. Endovascular stents can palliate symptoms in a high proportion of patients.
- Central nervous system or spinal metastases can often be managed on an outpatient basis with dexamethasone and radiation treatment. Individual patients may benefit from higher doses of dexamethasone (up to 200 mg/day), and surgery with radiation can achieve significant palliation for some patients.
- DIC is observed in a number of solid tumors and is the hallmark of APL. Serial levels of fibrin split products and fibrinogen will determine the amount of cryoprecipitate needed to replace consumed coagulation proteins. Heparin can be used in patients who do not respond to cryoprecipitate.
- Febrile neutropenia can often be managed outside the ICU with appropriate broad-spectrum antibiotic support. The choice of antibiotics should take into account the microbial pathogens most prevalent in the treating institution.
- Hypotension caused by IL-2 and other cytokines has a pathophysiology similar to that of septic shock, with the induction of nitric oxide and other vasoactive mediators. Phenylephrine is an effective pressor agent for IL-2–induced hypotension. Glucocorticoids may be useful in patients with circulatory collapse or ARDS from IL-2 or other immunotherapy.
- Infections that occur during bone marrow transplant are related to the recovery of different parts of immune function after transplant. Aerobic bacteria and *Candida* infections are most prevalent early, when mucosal barriers are disrupted by myeloablative chemotherapy. Herpes simplex, *Candida*, bacterial, and *Aspergillus* infections are common until neutrophil recovery has occurred. Varicella zoster, hepatitis C, and *Pneumocystis jiroveci* infections are observed up

KEY POINTS (Continued)

- to 3 months after transplant until cellular immune function recovers.
- Immune-mediated colitis induced by ipilimumab can be life threatening. Early administration of high-dose glucocorticoids and fluid resuscitation are essential elements of management. Emergent surgery and ICU support may be necessary in some patients.
- A cancer diagnosis is not a contraindication to intensive care management. Dose-intense treatment modalities mandate intensive support and have resulted in improved outcomes for patients with malignancies.

CONDITIONS NOT SPECIFIC TO
PREGNANCY
Septic Shock
Acute Respiratory Distress Syndrome in
Pregnancy
Pulmonary Thromboembolic Disease
Asthma
Cardiac Disease
Trauma

Management of the critically ill pregnant patient is a situation with which few intensive care physicians gain significant expertise. The usual clinical approach may be altered by the physiologic changes induced by pregnancy, by the relatively uncommon pregnancy-specific conditions, and by perceived limitations on therapy produced by the presence of a fetus (Fig. 81.1).

PHYSIOLOGIC CHANGES IN PREGNANCY

The pregnant woman undergoes a number of physiologic changes affecting various systems relevant to critical care management. From a respiratory perspective, the upper airways develop edema and hyperemia, which may be relevant during endotracheal intubation. Changes in lung volumes occur, with a 10% to 25% decrease in functional residual capacity (FRC), whereas total lung capacity decreases only minimally as the thoracic cage widens to compensate.¹ Forced expiratory volume in 1 second (FEV₁) is not altered by the pregnant state. Lung compliance remains unchanged, but chest wall and total respiratory compliance are reduced.²

The rising progesterone level stimulates an increase in ventilation. Tidal volume and minute ventilation increase from the first trimester, reaching 20% to 40% above

baseline by term (Table 81.1).³ A mild respiratory alkalosis is produced with compensatory renal excretion of bicarbonate (Paco₂ 28 to 32 mm Hg; HCO₃⁻ 18 to 21 mEq/L). Oxygen consumption increases because of the demands of the fetus and maternal metabolic processes, reaching levels up to 33% above baseline by term. Arterial Po₂ remains normal throughout pregnancy, but mild hypoxemia caused by an increased alveolar-arterial oxygen tension difference may develop in the supine position, as FRC diminishes near term.

Maternal blood volume and cardiac output increase through pregnancy, reaching a peak at 30% to 50% above baseline levels by about 28 weeks (Fig. 81.2).⁴ Hemodynamic measurements by pulmonary artery catheter in the near-term patient demonstrate the increased cardiac output, with a reduced systemic vascular resistance and pulmonary vascular resistance (see Table 81.1).⁵ During labor and continuing into the immediate postpartum period, cardiac output is further augmented by the return of 300 to 500 mL of blood to the central circulation.⁶

Oxygen delivery to the fetus is dependent on the maternal arterial oxygen content and the uterine blood flow. Maternal hypotension, alkalosis (e.g., hyperventilation), and endogenous or exogenous catecholamines can vasoconstrict the uterine artery and adversely affect fetal oxygenation.⁷ Uterine blood flow is also reduced transiently by

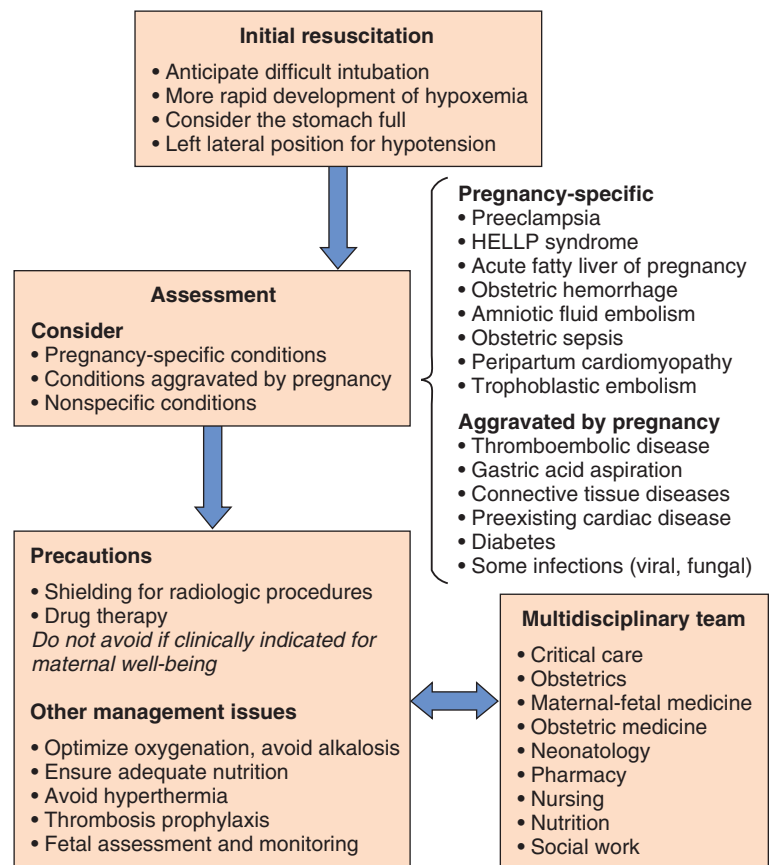

Figure 81.1 Approach to the assessment and management of the critically ill obstetric patient.

Table 81.1 Physiologic Changes in Late Pregnancy

Parameter	Change
Respiratory	
Functional residual capacity	Decreased 10-25%
Minute ventilation	Increased 20-40%
Arterial partial pressure of oxygen	No change
Arterial partial pressure of carbon dioxide	Reduced to 28-32 mm Hg
Serum bicarbonate	Reduced to 18-21 mEq/L
Cardiac	
Heart rate	Increased 10-30%
Pulmonary capillary wedge pressure	No change
Cardiac output	Increased 30-50%
Systemic vascular resistance	Decreased 20-30%
Pulmonary vascular resistance	Decreased 20-30%
Renal	
Glomerular filtration rate	Increased 50%
Creatinine	Decreased (24-68 $\mu\text{mol/L}$; 0.29-0.77 mg/dL)

uterine contractions. Although umbilical venous blood returning to the fetus has a relatively low oxygen tension, a high oxygen content is maintained by the left shift of the oxygen dissociation curve of fetal hemoglobin.

Glomerular filtration rate increases early in pregnancy, reaching a value 50% above prepregnancy levels in the second trimester, and remains elevated throughout pregnancy (see Fig. 81.2).⁸ The normal serum creatinine level is therefore in the range of 0.5 to 0.7 mg/dL (45 to 60 $\mu\text{mol/L}$). As pregnancy progresses, mild ureteric dilation and mild hydronephrosis may occur as a result of uterine compression and smooth muscle relaxation.

Pregnancy is associated with a reduced lower esophageal sphincter pressure, reaching a nadir at 36 weeks. The position of the stomach is displaced, further decreasing the effectiveness of the gastroesophageal sphincter and reducing gastric emptying. The pregnant woman should therefore always be considered at risk for aspiration of stomach contents, regardless of the time elapsed since her last meal.

The increase in plasma volume is associated with a lesser increase in red blood cell mass causing a physiologic anemia, with a hematocrit of 32% to 34% by the third trimester. A mild leukocytosis occurs with white blood cell count rising further during labor. Platelet counts are usually unchanged, although a condition of benign mild thrombocytopenia may occur.⁹ Procoagulant factors rise, contributing to the hypercoagulable state of pregnancy. The erythrocyte sedimentation rate (ESR) rises related to increased levels of plasma globulins.

Figure 81.2 Graphic representation of some of the physiologic changes that occur in pregnancy. CO, cardiac output; FRC, functional residual capacity; GFR, glomerular filtration rate; VE, minute ventilation. (From Lapinsky SE, Kruczynski K, Slutsky AS: Critical care in the pregnant patient. *Am J Respir Crit Care Med* 1995;152:427-455.)

CRITICAL CARE MANAGEMENT

GENERAL CARE

POSITIONING

In the supine position the gravid uterus produces mechanical effects on the vena cava and aorta, reducing central venous return. This results in a decrease in cardiac output and hypotension. This “supine hypotensive syndrome” should be considered in hemodynamically unstable patients.¹⁰ Pregnant patients should be positioned on their left side, or at least with the right hip slightly elevated.

NUTRITION

During starvation, maternal body stores are protected at the expense of the fetus and inadequate nutrition may result in intrauterine growth retardation and fetal loss. Growth restriction before 26 weeks’ gestation may lead to fetal neurologic impairment. Caloric requirements in pregnancy increase by about 300 kcal/day, and protein intake should

be augmented by 20% to 50%. Several nutrients have an increased requirement in pregnancy including iron, folate, and calcium. Total parenteral nutrition (TPN) has been used successfully to provide nutritional support during pregnancy in the patient in whom enteral nutrition is not possible. Blood glucose should be measured frequently in view of the predisposition to hyperglycemia.

THROMBOSIS PROPHYLAXIS

Pregnancy increases the risks of venous thrombosis caused by hypercoagulability and venous stasis. Antithrombotic measures including physical interventions and heparin prophylaxis should be considered.

RADIOLOGIC PROCEDURES AND FETAL RISK

Radiologic investigations are often essential for the assessment and management of the critically ill pregnant patient. Although there are potential risks of exposing the fetus to ionizing radiation, fetal well-being depends on maternal recovery, and appropriate radiologic procedures should not

Table 81.2 Risk of Fetal Radiation Exposure Resulting from Radiologic Studies in the Critically Ill Pregnant Patient

Investigation	Fetal Radiation Exposure (mGy)
Chest radiograph (with abdomen shielded)	0.01
Ventilation-perfusion scan	
Perfusion	0.1-1
Ventilation	0.1-0.4
CT pulmonary angiogram	0.1-4
CT scan of pelvis and abdomen	30-50
Radiation effect on fetus	
Teratogenicity	50-100
Oncogenicity	20-50

CT, computed tomography.

be avoided. Techniques such as shielding the abdomen with lead and using a well-collimated x-ray beam can effectively reduce exposure. With these precautions, estimated fetal radiation exposure can be limited to safe levels for most procedures, although investigations such as abdominal-pelvic computed tomography (CT) will obviously cause significant fetal radiation exposure (Table 81.2).¹¹

The adverse effects of fetal exposure to radiation include oncogenicity and teratogenicity. A twofold increased risk of childhood leukemia may result from fetal exposure in the range of 20 to 50 mGy (2 to 5 rads). Most intensive care unit (ICU) procedures can be carried out well below these levels of exposure to the fetus (see Table 81.2). Teratogenicity does not appear to occur at these radiation doses, requiring radiation exposure greater than 50 to 100 mGy (5 to 10 rads). Nonetheless, every effort should be made to minimize uterine exposure, particularly in the first trimester.

DRUG THERAPY IN PREGNANCY

Pharmacotherapy during pregnancy requires consideration of the altered drug clearance, metabolism, and volume of distribution of drugs in pregnancy, and the potential pharmacologic and teratogenic effects on the embryo. A detailed description of drug therapy in pregnancy is beyond the scope of this chapter. Consultation with an obstetrician and pharmacist is essential, and several excellent resources are available.^{12,13} Some common ICU drugs are discussed briefly as follows.

CATECHOLAMINES

Catecholamines commonly used in the ICU such as dobutamine, dopamine, norepinephrine, and epinephrine all have the potential to reduce uterine blood flow. Both ephedrine and phenylephrine boluses are used for transient hypotension induced by neuraxial anesthesia. Nonpharmacologic maneuvers such as volume replacement and left lateral positioning are essential to the management of hypotension, and the rapidity of correction of blood pressure may be more important than the specific inotropic agent

used. If vasopressor infusion therapy is required to support maternal hemodynamics, this therapy should not be withheld because of concerns for potential adverse effects on the fetus.

SEDATION, ANALGESIA, AND NEUROMUSCULAR BLOCKADE

Little data exist on the preferred drugs for prolonged sedation, analgesia, or neuromuscular blockade in pregnancy. Benzodiazepine use in early pregnancy has been associated with a small risk of congenital malformations, mainly cleft lip and palate. Midazolam crosses the placenta to a lesser degree than diazepam, which can accumulate in the fetus at levels greater than in the mother. Propofol has been used as an induction agent for cesarean section, but a single case report describes the development of non-anion gap acidosis in two pregnant women receiving propofol infusion for neurosurgical procedures.¹⁴ Congenital malformations have not been demonstrated with use of narcotic analgesics such as morphine, meperidine, and fentanyl. The majority of nondepolarizing neuromuscular blocking agents have been shown to cross the placenta including pancuronium, vecuronium, and atracurium, but transfer is unlikely to have clinical effects on the fetus in the short term. Nevertheless, if sedative or paralyzing agents are used in the pregnant woman, this information must be communicated to the neonatologist, who should anticipate the need for ventilatory support for the fetus.

ANTIBIOTICS

Antibiotic regimens similar to those used in the nonpregnant patient are appropriate, with some precautions. Quinolones should probably be avoided because of the potential risk of arthropathy. Tetracyclines produce adverse effects on fetal teeth and bone, and aminoglycosides and sulfonamides should be used with caution.

FETAL OXYGENATION AND MONITORING

Attention to interventions aimed at optimizing fetal oxygenation is important in the management of any critically ill pregnant patient. Depending on gestational age, delivery of the fetus may be the most appropriate intervention. Uteroplacental oxygen delivery can be optimized by increasing oxygen carrying capacity—by blood transfusion, improving maternal cardiac output, and optimizing maternal oxygenation. The simple maneuver of tilting the patient to the left lateral position to increase cardiac output should always be considered.¹⁰

Continuous electronic monitoring of fetal heart rate (FHR) can be used to identify changes in fetal physiology. Abnormal patterns of FHR have been described with good sensitivity but varying specificity for fetal distress. Fetal tachycardia may occur in the presence of maternal infection or chorioamnionitis, but fetal bradycardia or sinusoidal variation in FHR are more ominous, suggesting fetal hypoxia. Changes in FHR occur in response to uterine activity. Early decelerations coinciding with contractions are benign, but late decelerations beginning beyond the peak in contraction and persisting after the contraction may indicate fetal compromise, particularly if associated with a reduced beat-to-beat variation. Fetal compromise may occur

as a result of uteroplacental or fetal pathology but may also indicate maternal illness with reduced uterine oxygen delivery. The fetus may be further assessed by an ultrasound biophysical profile that evaluates factors such as spontaneous movement, breathing action, and amniotic fluid volume. A normal biophysical profile carries a good prognosis.

HEMODYNAMIC MONITORING

In general the indications for use of the pulmonary artery catheter are similar to those in nonobstetric patients, and pregnancy is not a contraindication to invasive hemodynamic monitoring. An awareness of the normal cardiovascular physiologic changes in pregnancy (discussed earlier) is necessary in order to correctly interpret the hemodynamic data obtained.

VENTILATORY SUPPORT

NONINVASIVE VENTILATION

Noninvasive ventilation avoids the adverse effects of endotracheal intubation, such as airway trauma, the increased risk of nosocomial pneumonia, and the complications associated with sedation. This modality is ideally suited to short-term ventilatory support, which is the case in many obstetric complications that reverse rapidly. The major concern with mask ventilation in pregnancy is the risk of aspiration because of the increased intra-abdominal pressure, delayed gastric emptying, and reduced lower esophageal sphincter tone accompanying pregnancy. Noninvasive ventilation should therefore be reserved for the patient who is alert, protecting her airway, and has an expectation of a relatively brief requirement for mechanical ventilatory support.

AIRWAY MANAGEMENT

Failed intubation is more common in the obstetric population than in other anesthetic intubations.¹⁵ The reduced oxygen reserve caused by diminished FRC and increased oxygen consumption produces rapid desaturation in response to apnea or hypoventilation.¹⁶ Preoxygenation with 100% oxygen is beneficial, but respiratory alkalosis must be avoided. In view of the delayed gastric emptying and elevated intra-abdominal pressure, the pregnant patient should always be considered to have a full stomach and appropriate precautions should be taken. Upper airway hyperemia and edema may reduce visualization and necessitate use of a smaller endotracheal tube. The risk of bleeding is increased and nasal intubation should be avoided.

MECHANICAL VENTILATION

The normal P_{aCO_2} of about 30 mm Hg in late pregnancy should be considered in the interpretation of arterial blood gases when decisions are made to institute ventilatory support. Data on the prolonged mechanical ventilation of pregnant patients are limited. Hyperventilation should be avoided because this adversely affects uterine blood flow¹⁷ because of the resulting alkalemia as well as the effect of positive-pressure ventilation in reducing cardiac output. The current ventilatory approach of avoiding excessive lung stretch by pressure limitation and permissive hypercapnia has not been assessed in pregnancy. The usual pressure limits (e.g., plateau pressure of 35 cm H₂O) may not be

applicable in the near-term patient, in whom chest wall compliance is reduced. Transpulmonary pressures may not be elevated at a plateau pressure of 35 cm H₂O, and higher ventilatory pressures may be acceptable in pregnant patients near term. Although late pregnancy is associated with a mild respiratory alkalosis, maternal hypercapnia up to 60 mm Hg in the presence of adequate oxygenation does not appear to be detrimental to the fetus.¹⁸ Maternal hypercapnia and respiratory acidosis may produce fetal acidosis, but this does not have the same ominous implications as fetal acidosis due to lactic acidosis resulting from fetal hypoxia.¹⁹ However, acidosis produces a right shift of the hemoglobin oxygen dissociation curve, which may negate the beneficial oxygen-carrying characteristics of fetal hemoglobin. If marked respiratory acidosis results from permissive hypercapnia, treatment with bicarbonate may improve maternal and fetal acidemia.

It may be considered that, because of the effects of pregnancy on respiratory physiology, delivery of the pregnant patient will result in improvement in the mother's respiratory status.²⁰ Limited case series addressing this issue have not found a significant benefit to the mother, and delivery carries a risk of harm.^{21,22} Some improvement in oxygenation has been noted, but without improvement in respiratory system compliance or reduction in positive end-expiratory pressure (PEEP) level.²⁰ Delivery is therefore not indicated purely in the hope of improving "maternal condition." If the fetus is considered viable but is at risk due to severe maternal hypoxia, consultation with a neonatologist may identify a benefit to the fetus in being delivered. Obstetric indications should always determine the mode of delivery.

CARDIOPULMONARY RESUSCITATION

Cardiopulmonary resuscitation requires only minor modifications from standard protocols.²³ Intravenous access should be established above the diaphragm owing to potentially impeded inferior vena caval blood flow. Electrical cardioversion and defibrillation may be performed in pregnancy, but fetal monitoring leads should be removed to prevent electrical arcing. Management in the supine position may cause aortocaval compression, resulting in impaired venous return and inadequate cardiac output. Manual displacement of the uterus to the left should be used, or alternatively a 30-degree left lateral tilt, which may impede cardiac compressions. Appropriate pharmacologic therapy should not be withheld if clinically indicated. Perimortem cesarean section may save the fetus when initial attempts at resuscitation have failed in a woman with a fetus at a viable gestation. Data suggest that infant survival without neurologic sequelae is highest if the postmortem cesarean section is initiated within 4 minutes of cardiac arrest, aiming for delivery within 5 minutes of arrest.

PREGNANCY-SPECIFIC CONDITIONS REQUIRING INTENSIVE CARE UNIT CARE

PREECLAMPSIA

Preeclampsia is a pregnancy-induced condition usually occurring after 20 weeks' gestation, characterized by

hypertension and proteinuria.²⁴ The cause remains unknown but is likely related to a placental abnormality producing a diffuse maternal endothelial effect, which leads to vaso-spasm and reduced organ perfusion (Fig. 81.3). Preeclampsia and its complications account for 20% to 50% of obstetric admissions to the ICU.²⁵⁻²⁷ Less common multisystem diseases should be considered in the differential diagnosis including systemic lupus erythematosus (SLE), thrombotic thrombocytopenic purpura (TTP), and hemolytic-uremic syndrome (HUS) (Table 81.3). Complications of preeclampsia may result in critical illness including pulmonary edema, cerebral edema, renal failure, hypertensive crisis, seizures (eclampsia), and the HELLP (hemolysis, elevated

liver enzymes, low platelet count) syndrome (microangiopathic hemolytic anemia, thrombocytopenia, and hepatic involvement).²⁸

The only specific treatment is delivery of the fetus and placenta. Delivery is always in the best interest of the mother, but timing may depend on fetal maturity. The role of anti-hypertensive therapy is to prevent maternal hypertensive complications, and it does not alter the natural history of the condition or benefit the fetus.²⁹ Commonly used agents include intravenous hydralazine or labetalol, as well as oral calcium antagonists.²⁴ Rapid reduction in blood pressure should usually be avoided because of the risk of reducing uteroplacental perfusion. Magnesium sulfate is used for seizure prophylaxis and treatment, giving an initial intravenous bolus (2 to 4 g) followed by an infusion of 1 to 3 g/hour. Toxic magnesium levels may occur (>3.5 mmol/L), particularly in the presence of renal dysfunction, producing respiratory muscle weakness and cardiac conduction defects. Hypocalcemia may be noted during magnesium infusion and should not be corrected routinely because this would negate the therapeutic effects of magnesium. Fluid management in preeclampsia usually requires careful volume expansion, but excessive fluid administration can cause pulmonary or cerebral edema.

HELLP SYNDROME

The HELLP syndrome is a condition associated with preeclampsia, characterized by the development of a microangiopathic hemolytic anemia and a consumptive thrombocytopenia.²⁸ Reduced hepatic perfusion results in periportal and focal parenchymal necrosis, elevated liver enzymes, and rarely hepatic hemorrhage or rupture. The clinical presentation is often with epigastric or right upper quadrant pain, nausea, vomiting, or evidence of bleeding.

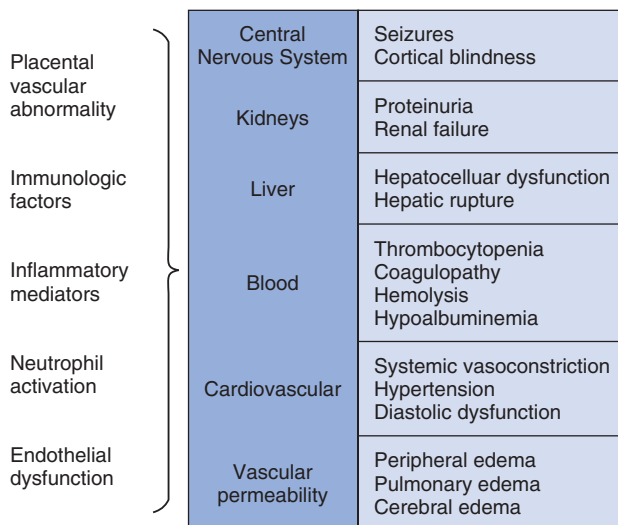

Figure 81.3 Pathophysiology and multiorgan effects of preeclampsia.

Table 81.3 Differential Diagnosis of Pregnancy-Related Complications

Clinical Finding	Pregnancy-Specific Complications	Nonspecific Complications
1. Hypertension	Preeclampsia	Essential hypertension Secondary hypertension (renal, pheochromocytoma)
2. Thrombocytopenia	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy	TTP ITP Sepsis SLE
3. Abnormal liver enzymes	Preeclampsia HELLP syndrome Acute fatty liver of pregnancy Cholestasis of pregnancy	Viral hepatitis Drug-induced hepatitis Budd-Chiari syndrome
4. Renal dysfunction	Preeclampsia Acute fatty liver of pregnancy Idiopathic postpartum renal failure	Sepsis Hypovolemia/hemorrhage TTP/HUS SLE
5. Pulmonary edema	Preeclampsia Peripartum cardiomyopathy Tocolytic pulmonary edema Amniotic fluid emboli	Valvular heart disease Ischemic heart disease ARDS Aspiration

ARDS, acute respiratory distress syndrome; HELLP, hemolysis, elevated liver enzymes, low platelet count; HUS, hemolytic-uremic syndrome; ITP, idiopathic thrombocytopenic purpura; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

Features of preeclampsia do not occur in all patients, and approximately 30% of patients with HELLP develop the disease only in the postpartum period.

The diagnosis is based on the presence of thrombocytopenia ($<100 \times 10^9$ cells/L), with a moderate elevation of liver enzymes, and microangiopathic hemolytic anemia (increased lactate dehydrogenase, bilirubin, abnormal blood smear). Many patients are found to have a more widespread coagulation defect than just thrombocytopenia. White blood cell count may be elevated, and hypoglycemia is uncommon, in contrast to acute fatty liver of pregnancy (AFLP).

Management includes early delivery if the fetus is viable, blood product support, and management of associated preeclampsia. Dexamethasone initiated prior to delivery has been reported to produce more rapid recovery of thrombocytopenia in some studies but this was not confirmed in the most recent study.^{30,31} Delivery may require platelet support, and if cesarean section is necessary, hemorrhage should be anticipated and adequate drains should be inserted. Epidural anesthesia is usually contraindicated in the presence of thrombocytopenia.

The maternal complications of HELLP include hemorrhage, acute respiratory distress syndrome (ARDS), and acute renal failure. An uncommon but catastrophic consequence of the HELLP syndrome is hepatic subcapsular hemorrhage, which occurs in about 2% of patients and can progress to hepatic rupture. Hepatic rupture should be considered in any preeclamptic patient with sudden shock or acute abdominal pain. Management requires aggressive hemodynamic and blood product support, urgent delivery, and invasive control of the hemorrhage with embolization, or laparotomy with packing of the liver. Hemorrhage without rupture may be managed conservatively if the patient remains hemodynamically stable.

Significant overlap exists between HELLP and other multisystem conditions and thrombotic microangiopathies (see Table 81.3). A response to plasmapheresis may be noted in some patients, possibly representing those with TTP or HUS rather than HELLP. Plasmapheresis is recommended for patients with delayed postpartum resolution when severe thrombocytopenia, hemolysis, or organ dysfunction persist more than 72 hours following delivery. The maternal mortality rate for women with HELLP syndrome is reported between 1% and 3% (with isolated reports as high as 25%) and with a significant perinatal mortality rate at 8% to 60%.

ACUTE FATTY LIVER OF PREGNANCY

AFLP is an uncommon condition affecting about 1 in 15,000 pregnancies. Although early reports described acute fulminant hepatic failure with high maternal and fetal mortality rates, the condition is now usually recognized at an earlier stage, allowing early delivery and a significantly improved outcome.³² Maternal mortality rate has been reported at 0% to 18% with fetal loss of 23% to 60%. The cause of this condition is unknown, but an association with a fetal inborn error of metabolism (L-CHAD [long-chain 3-hydroxyacyl-coenzyme A dehydrogenase] deficiency) has been described.³³ Pathologically, diffuse fatty infiltration of the liver occurs with necrosis and inflammation being mild or absent.

Patients usually present toward the end of the third trimester with a range of onset from as early as 30 weeks' gestation up until the puerperium. Prodromal symptoms of malaise, anorexia, and vomiting may precede the onset of jaundice by 1 to 2 weeks. Abdominal pain may occur, which may be diffuse or localized to the right upper quadrant. Laboratory investigations demonstrate a moderate elevation in transaminase levels (e.g., 300 to 600 units), in contrast with the higher levels occurring in acute hepatitis. The white blood cell count is often elevated and thrombocytopenia and fragmented red blood cells may be demonstrated. Features of hepatic dysfunction such as hypoalbuminemia, hypoglycemia, and coagulopathy occur in more severe cases.

The differential diagnosis of liver disease in pregnancy is wide, and the multisystemic effects of AFLP may resemble systemic lupus, TTP, or HUS (see Table 81.3).

The definitive treatment is delivery of the fetus, and early recognition of this condition is responsible for an improved outcome. Because the presentation is usually close to term, the decision is usually easy and carries little additional risk for the fetus. However, AFLP is associated with placental insufficiency because of fibrin deposition, producing increased fetal loss. It has been reported that this process may be exacerbated by therapeutic coagulation factor replacement. Supportive therapy is similar to that for other causes of fulminant hepatic failure including correction of coagulation abnormalities and hypoglycemia. Hepatic encephalopathy requires attention to airway protection, dietary protein restriction, bowel sterilization, and oral or rectal lactulose administration. Transient worsening of hepatic function may occur following delivery with improvement usually beginning within 2 to 3 days. A small subset of patients continue to deteriorate following delivery, and liver transplantation may be indicated. Complications such as hemorrhage, pancreatitis, renal failure, diabetes insipidus, and infection should be sought and treated.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism is a catastrophic cardiopulmonary complication of pregnancy, carrying a mortality rate of 10% to 86%.³⁴ It usually occurs in association with labor and delivery but may be precipitated by uterine trauma or manipulations. Amniotic fluid enters the venous circulation and particulate contents or humoral factors produce acute pulmonary hypertension, as well as acute left ventricular dysfunction.³⁵ The pregnant woman develops sudden onset of dyspnea, hypoxemia, and cardiovascular collapse. The presenting feature may sometimes be seizures related to cerebral hypoxia or acute fetal hypoxia and distress. Many patients with amniotic fluid embolism die within the first hour. No specific diagnostic test is available, and the diagnosis of amniotic fluid embolism is based on a typical clinical picture and exclusion of other conditions such as septic shock, pulmonary thromboembolism, abruptio placentae, tension pneumothorax, or a myocardial ischemic event.

Treatment involves routine resuscitative and supportive measures including mechanical ventilation and inotropic therapy. A role for corticosteroids has been suggested on the basis of the hypothesis that the process may involve an anaphylactoid reaction to amniotic fluid contents.³⁴

Survivors of the initial process may develop disseminated intravascular coagulation (DIC) and ARDS. Neurologic damage caused by the initial hypotension and hypoxemia is common.

OBSTETRIC HEMORRHAGE

Uterine blood flow reaches 600 mL/minute near term, subjecting the pregnant patient to the risk of devastating blood loss. Antepartum hemorrhage occurs from disruption of the placenta, such as with placental abruption or a low-lying placenta (placenta previa) as the cervix dilates. Most hemorrhage occurs postpartum because of uterine atony, cervical or vaginal lacerations, or related to antepartum hemorrhage, or associated with coagulopathy. The pregnant woman is physiologically prepared for blood loss and tolerates the loss from a normal vaginal delivery (600 mL) or cesarean section (1000 mL). However, excessive blood loss will result in hypovolemic shock with compromise to fetus and vital organs. The pregnant woman is particularly susceptible to hypoperfusion injury to the kidney. A high incidence of myocardial ischemia has been noted in pregnant women with hemorrhagic shock.

Supportive management of obstetric hemorrhage is similar to that for any cause of hemorrhage and involves rapid volume replacement, supplemental oxygen administration, and red blood cell and blood product support for an associated dilutional coagulopathy. Various pharmacologic agents are utilized to control uterine bleeding. Intramuscular administration of methylergonovine (0.2 mg) may be useful in the presence of uterine atony but is contraindicated in the presence of hypertension.³⁶ Oxytocin is infused intravenously in a dose greater than that used for augmentation of labor, up to 100 mU/minute (e.g., 40 U in 1000 mL normal saline at 150 mL/hour). This dose may produce an antidiuretic effect and cause hyponatremia. A prostaglandin $F_{2\alpha}$ analog (carboprost tromethamine—Hemabate) given intramuscularly (0.25 mg, repeated every 15 to 90 minutes to maximum 2 mg) or intramyometrially, is effective in controlling hemorrhage.^{36,37} Side effects include vomiting, hypertension, bronchoconstriction, and increased intrapulmonary shunt. Obstetricians are increasingly using intrauterine balloon devices to tamponade bleeding.³⁸ Antibiotic prophylaxis is often given while the balloon is in place and analgesia is essential.

Isolated reports suggest that recombinant factor VIIa may be useful in the management of severe obstetric hemorrhage.³⁹ If the above-mentioned methods fail to control bleeding, radiologic transcatheter embolization of the internal iliac or uterine artery is usually effective.⁴⁰ Surgical exploration with arterial ligation or hysterectomy may become necessary.

PERIPARTUM CARDIOMYOPATHY

Cardiac failure may occur in the absence of preexisting heart disease because of peripartum cardiomyopathy. This idiopathic condition presents in the last month of pregnancy or within 5 months of delivery, with an incidence of approximately 1 in 3500 live births.⁴¹ The clinical presentation is usually after 36 weeks' gestation (in contrast to women with preexisting cardiac disease) and involves the

gradual onset of symptoms of heart failure. The diagnosis is made by the demonstration of left ventricular systolic dysfunction and by the exclusion of other causes of cardiomyopathy. During labor and the early postpartum period, tachycardia and increased cardiac output may precipitate acute pulmonary edema.

Treatment is similar to other patients with cardiac failure, although angiotensin-converting enzyme (ACE) inhibitors should be avoided before delivery. Anticoagulation is essential because of the hypercoagulable state of pregnancy and the high incidence of thrombotic complications. A subset of patients may have an inflammatory myocarditis, and immunosuppressive therapy may be considered in those who do not improve after 2 weeks of standard treatment.⁴¹ Although a high mortality rate has been described (10% to 50%), about half of patients recover normal ventricular function.⁴²

TOCOLYTIC PULMONARY EDEMA

β -Adrenergic blockers can be used to inhibit uterine contractions in preterm labor, although this is less frequently used because studies have demonstrated a lack of fetal benefit from this practice. A complication of this β -agonist therapy in pregnancy is the development of acute pulmonary edema.⁴³ Treatment involves discontinuing the β -agonist and supportive treatment including diuresis and oxygen therapy. Failure of the pulmonary edema to resolve within 24 hours should prompt a search for an alternative diagnosis (Table 81.4).

GESTATIONAL TROPHOBLASTIC DISEASE

Pulmonary hypertension and pulmonary edema may occur in the setting of benign hydatidiform mole, as a result of trophoblastic pulmonary embolism. This most commonly occurs during evacuation of the uterus, with a higher incidence of pulmonary complications in the woman later in pregnancy.⁴⁴ With supportive treatment resolution occurs within 48 to 72 hours. Molar pregnancy may also be associated with choriocarcinoma, which can produce multiple, discrete, pulmonary metastases.

CONDITIONS NOT SPECIFIC TO PREGNANCY

SEPTIC SHOCK

Changes occur in the immune status in pregnant women, facilitating tolerance to paternally derived fetal antigens. An altered T_H1/T_H2 balance occurs, with the maternal immune response favoring humoral immunity (T_H2 response), and suppressing cell-mediated immunity (T_H1 response), which could be harmful to the fetus.⁴⁵ This altered immune response may predispose pregnant women to increased incidence or severity of certain infections, including *Listeria monocytogenes* infection, disseminated herpesvirus infections, varicella, and coccidioidomycosis infections. Human immunodeficiency virus infections should always be considered. Obstetric sepsis in the antepartum period produces chorioamnionitis, but most obstetric sepsis occurs in

Table 81.4 Differential Diagnosis of Acute Respiratory Distress in Pregnancy

Disorder	Distinguishing Features
Pregnancy-Specific	
Amniotic fluid embolism	Cardiorespiratory collapse, seizures, DIC
Pulmonary edema secondary to preeclampsia	Hypertension, proteinuria
ARDS secondary to obstetric sepsis	Evidence of obstetric sepsis, shock
Tocolytic pulmonary edema	Tocolytic administration, rapid improvement
Peripartum cardiomyopathy	Gradual onset, cardiac gallop, cardiomegaly
Trophoblastic embolism	Nodular infiltrate, molar pregnancy
Risk Increased by Pregnancy	
Aspiration pneumonitis	Vomiting, aspiration
Venous thromboembolism	Evidence of DVT, positive \dot{V}/\dot{Q} scan, leg Doppler studies, CT angiogram
Pneumomediastinum	Occurs during delivery, subcutaneous emphysema
Valvular heart disease	Pulmonary edema, cardiac murmur, cardiomegaly
ARDS secondary to sepsis	Evidence of sepsis (e.g., pyelonephritis)
Unrelated to Pregnancy	
Asthma	Features similar to those in nonpregnant patient
Pneumonia	Features similar to those in nonpregnant patient

ARDS, acute respiratory distress syndrome; CT, computed tomography; DIC, disseminated intravascular coagulation; DVT, deep vein thrombosis; \dot{V}/\dot{Q} , ventilation-perfusion.

the postpartum period. The most common location of infection is the placental site, causing endometritis, which can spread to become a peritonitis. Episiotomy sites or cesarean section wounds may also become infected. Infections often involve a mixed flora, with microorganisms originating from the vagina (e.g., anaerobes, group B streptococci), intestine (gram-negative organisms, enterococci, anaerobes), sexual transmission (e.g., *Neisseria gonorrhoeae*), or hematogenous spread (e.g., *Listeria*, group A streptococci).⁴⁶

Management of septic shock is similar to that in the nonpregnant patient, with prompt resuscitation with volume expansion. If inotropic therapy is necessary in the antepartum patient, the effects of such drugs on uteroplacental perfusion should be considered. Adequate specimens for culture should be obtained including amniocentesis in the antepartum patient. Ultrasonography may be valuable to identify a source of localized infection and exclude retained products of conception.

Initial empiric antibiotic therapy should provide broad gram-negative, gram-positive, and anaerobic cover. Common regimens use drugs such as ampicillin, gentamicin, and

clindamycin; ampicillin/sulbactam; ticarcillin/clavulanate; piperacillin and gentamicin; or carbapenems.⁴⁷ Urgent delivery may be required for management of chorioamnionitis with sepsis syndrome.

A poor response to antibiotic therapy may indicate a resistant organism (e.g., *Enterococcus*), a localized abscess, myometrial microabscesses, or septic pelvic thrombophlebitis. Gas in the subcutaneous tissues or uterine wall suggests clostridial gas gangrene. Patients with retained products or devitalized tissue are at significant risk. Toxic shock caused by *Staphylococcus aureus* or *Clostridium sordelli* may occur, often associated with septic abortion. Surgical evacuation of the uterus or laparotomy with débridement or even hysterectomy may be required. Puerperal ovarian vein thrombophlebitis may complicate endometritis, presenting with acute deterioration with fever. The diagnosis can be confirmed with CT or magnetic resonance imaging scanning, and treatment requires anticoagulation and antibiotic therapy. Surgical intervention with venous ligation or excision may be required.

Group A streptococcal necrotizing fasciitis and toxic shock syndrome have been reported to occur unexpectedly following an uncomplicated pregnancy and delivery.⁴⁸ Management includes antibiotic therapy with penicillin and clindamycin and early surgical intervention. Intravenous immunoglobulin (2 g/kg) may be beneficial.

ACUTE RESPIRATORY DISTRESS SYNDROME IN PREGNANCY

The pregnant patient is at risk of developing acute lung injury from pregnancy-associated complications and other conditions (see Table 81.4).⁴⁹ The pregnant patient appears to be at increased risk of developing pulmonary edema because of the cardiovascular changes, the reduced albumin level occurring in pregnancy, increased capillary leak, and possibly an upregulation of components of the acute inflammatory response.

Management is similar to that in the nonpregnant patient. Adequate maternal oxygenation is essential for fetal well-being, and delivery may benefit both the mother and the fetus.⁵⁰ Survival from ARDS is as good as or better than that in the general population, likely because of these patients' young age, lack of comorbid conditions, and the reversibility of many of the predisposing conditions.

PULMONARY THROMBOEMBOLIC DISEASE

Pulmonary thromboembolism is a leading cause of maternal death. Although the risk is significantly increased in pregnant women because of increased coagulation factors, hormonally mediated venous stasis, and local pressure effects, the incidence is relatively low at about 1 per 1000 deliveries. Pulmonary embolism occurs most frequently in the early postpartum period.

Investigation of suspected pulmonary embolism is not different from that in the nonpregnant patient, with duplex ultrasound as the initial investigation. False positives may occur with Doppler alone because of venous obstruction by the gravid uterus. Ventilation-perfusion scanning and CT pulmonary angiography can be performed with low risk of fetal radiation exposure (see Table 81.2).¹¹

Warfarin is generally avoided in pregnancy because of the risk of a first trimester embryopathy and central nervous system abnormalities with second- and third-trimester exposure. Heparin does not cross the placenta and can be readily reversed, and low-molecular-weight heparins are safe and effective in pregnancy although less easy to reverse acutely.⁵¹ Thrombolysis has been used successfully in pregnancy but should be limited to life-threatening situations. Transvenous inferior vena caval filters have been used in the pregnant patient, although there is a risk of dislodgement because of venous dilation and pressure effects.

ASTHMA

The hormonal changes of pregnancy can affect asthma variably, with worsening, improvement, or no substantial change occurring. Asthma is a common condition, and acute asthmatic attacks are therefore an important cause of respiratory compromise in pregnancy. In assessment of the patient with a severe acute attack, the reduced Paco_2 occurring in late pregnancy should be considered; a normal Paco_2 level associated with acidosis may imply respiratory failure. Treatment is similar to the nonpregnant patient, including β -agonists and corticosteroids. Although there is a natural reluctance to prescribe drug therapy in these patients, pregnancy is not an absolute contraindication to systemic corticosteroid therapy.⁵² Uncontrolled asthma is more dangerous to the fetus than appropriate drug therapy, and management should highlight the importance of adequate oxygenation.

CARDIAC DISEASE

Overt or occult preexisting heart disease may produce acute cardiac decompensation as the blood volume and cardiac output increase during pregnancy. Women with prior cardiac events, cyanotic disease, or pulmonary hypertension are at particular risk. Patients with mitral and aortic stenosis are at risk of developing hemodynamic deterioration as the physiologic changes peak at about 28 weeks, but mild to moderate regurgitant valvular disease is generally well tolerated.⁵³ The onset of atrial fibrillation or severe hypertension can precipitate sudden hemodynamic deterioration even in those women with less severe cardiac disease.

Patients with moderate to severe mitral stenosis are likely to experience hemodynamic deterioration during the third trimester or during labor. Treatment is similar to the nonpregnant patient using digoxin and beta blockers to control heart rate and diuretics to reduce left atrial pressure.⁵⁴ ACE inhibitors should be avoided. Most patients with mitral stenosis can undergo vaginal delivery with consideration to invasive hemodynamic monitoring during labor and the early postpartum period. Epidural anesthesia is usually better tolerated hemodynamically than general anesthesia during labor and delivery. Electrical cardioversion can be performed safely if indicated.

Severe aortic stenosis is associated with significant risk during pregnancy,⁵⁴ with symptoms such as dyspnea, angina, or syncope appearing from late in the second trimester. Percutaneous aortic balloon valvuloplasty can be performed during pregnancy. Spinal and epidural anesthesia during

labor may adversely affect hemodynamics because of the vasodilatory effects.

Ischemic heart disease is uncommon in pregnancy but may be missed because of masking of the symptoms, signs, and cardiac enzyme levels by pregnancy. Coronary artery dissection may occur, particularly in the immediate postpartum period. Aortic dissection may occur related to hypertension, aortic coarctation, or Marfan syndrome and is associated with significant maternal and fetal death.⁵⁵

Women with cyanotic congenital heart disease, particularly those with associated pulmonary hypertension, are at significant risk during pregnancy. Because of the inability of the right ventricle to tolerate the increases in cardiac output, primary or secondary pulmonary hypertension is associated with a high mortality rate in pregnancy.⁵⁶ New specific treatments are now available, and although clinical trials in pregnancy are lacking, mortality rate appears to be decreasing to some degree.⁵⁷ Vasodilators such as prostacyclin (inhaled or intravenous) or inhaled nitric oxide, as well as phosphodiesterase-5 inhibitors such as sildenafil, have been used successfully in pregnancy.^{58,59} Endothelin receptor antagonists (e.g., bosentan) are avoided because of potential teratogenicity, and anticoagulation is recommended for most patients. Patients with pulmonary hypertension should be managed in a center with expertise and experience in this area.

TRAUMA

The anatomic and physiologic changes of pregnancy may alter the manifestations and severity of traumatic injury. Uterine injury can produce severe hemorrhage because of the high uterine blood flow and may precipitate placental abruption or rarely uterine rupture. Uterine rupture manifests with maternal shock, abdominal pain, and palpable fetal parts. Penetrating injury to the abdomen predominantly affects the uterus in later pregnancy, but because intra-abdominal viscera are compressed in the upper abdomen, minor injury may result in significant damage.⁶⁰ Fractures of the pelvis can produce severe retroperitoneal hemorrhage because of dilation of pelvic veins.

Maternal trauma is associated with a significant increase in fetal loss, due to maternal shock or hypoxia, placental injury, or direct fetal injury.⁶¹ Direct fetal injury resulting from blunt trauma usually involves head injury related to maternal pelvic fracture. Other fetal injuries may occur following blunt or penetrating trauma, sometimes with minimal maternal injury. A high fetal mortality rate occurs in the presence of maternal burns to greater than 30% of the body surface area. Placental abruption is an important cause of fetal demise,⁶⁰ and may present with vaginal bleeding, abdominal cramps, uterine tenderness, amniotic fluid leakage, and unexplained fetal distress or maternal hypovolemia. Placental abruption is often complicated by DIC due to release of thromboplastin into the maternal circulation.

Evaluation of the pregnant trauma patient should include a detailed abdominal examination, but physical signs may be affected by changing organ position and the reduced peritoneal sensitivity that occurs in pregnancy.⁶² Initial investigations should include blood type including Rh status. Ultrasound is useful for evaluation of the fetus for injury and biophysical profile and to assess intra-abdominal organ

damage. Ultrasound-guided paracentesis or diagnostic peritoneal lavage (by open technique, above the uterus) may aid in detecting bowel perforation or intraperitoneal hemorrhage. Transplacental hemorrhage of fetal blood into the maternal circulation may occur and can result in fetal exsanguination and maternal Rh sensitization. Fetomaternal hemorrhage is detected by the Kleihauer-Betke test, which identifies fetal cells in the maternal blood smear, and can estimate the volume of fetal hemorrhage by the percentage of red blood cells of fetal origin. Fetal evaluation includes heart rate assessment by auscultation (possible from 20 weeks) or Doppler probe. Obstetric consultation and continuous fetal cardiotocography are important when the fetus is at a viable gestation.

Care of the severely injured pregnant patient requires a multidisciplinary approach involving the emergency physician, trauma surgeon, obstetrician, intensivist, and neonatologist. Initial resuscitation follows usual principles with efforts directed primarily at stabilizing the mother. Fluid replacement may need to be given more rapidly than in nonpregnant women because of the physiologic increase in plasma volume, and maternal blood pressure and heart rate may not be reliable predictors of the degree of hemorrhage.⁶² Left lateral positioning to prevent supine hypotensive syndrome is an important consideration in the hypotensive patient. Rh-negative mothers with abdominal trauma should receive Rh immune globulin even in the presence of a negative Kleihauer-Betke test. Higher doses of Rh immune globulin will be necessary in the presence of significant fetomaternal hemorrhage.

In the unstable mother, management of maternal injuries takes precedence over fetal distress because correction of maternal hemodynamics is beneficial to the fetus. The fetus is extremely vulnerable to hypotension and hypoxemia, and uterine blood flow will be markedly reduced when maternal circulation is compromised. If the mother is stable, cesarean section may be appropriate if the fetus is considered viable, the limits of viability being largely dependent on the level of neonatal care available.

KEY POINTS

- The reduced FRC and increased oxygen consumption in pregnancy result in rapid oxygen desaturation during apnea or intubation.
- Although there is a risk to the fetus from radiologic procedures and drug therapy, necessary investigations and treatment should not be withheld, with appropriate precautions.

KEY POINTS (Continued)

- The various pregnancy-specific conditions should be considered in the differential diagnosis of a critically ill pregnant woman including preeclampsia, HELLP syndrome, acute fatty liver of pregnancy, and amniotic fluid embolism.
- Hypotension may occur in the supine position in late pregnancy because of aortocaval compression—the clinician should position the hypotensive pregnant patient in the left lateral position.
- Management of preeclampsia, the commonest cause of ICU admission, involves delivery of the fetus, seizure prophylaxis with magnesium sulfate, correction of fluid balance, and treatment of hypertension if clinically significant.

MALNUTRITION

Malnutrition is a disorder in body composition in which inadequate macronutrient (protein, carbohydrate, and fat) or micronutrient (vitamins, minerals, and trace elements) intake results in decreased body mass, reduced organ mass, and most important, decreased organ function. Although malnutrition is most frequently associated with a risk for immune dysfunction-related infection, wound healing/fascial dehiscence, and breakdown of surgical anastomoses, it can affect virtually all organ systems when severe. Skeletal muscle wasting, decreased myocardial mass, diastolic cardiac dysfunction and decreased sensitivity to inotropic agents, respiratory insufficiency/need for prolonged mechanical ventilation, renal cortical atrophy, and loss of gastrointestinal absorptive/barrier functions have all been associated with malnutrition.

Malnutrition can occur as a result of combined protein-calorie deficiency (marasmus), predominantly protein deficiency (kwashiorkor), and deficiencies in specific micronutrients, as well as altered metabolism arising from a disease state such as sepsis, burns, or trauma. Critically ill patients may suffer from a combination of these causes. Malnutrition is thought to be present in as many as 25% to 50% of patients on hospital admission and may affect an additional 25% to 30% of patients during their hospital stay. The National Surgical Quality Improvement Program (NSQIP) has shown preoperative serum albumin, a measure of chronic nutritional status, to be an independent predictor of mortality risk in a study of more than 400,000 surgical

patients and specifically in patients undergoing colectomy, proctectomy, transurethral resection of bladder tumors, and major lung resection.¹⁻⁴ Malnutrition becomes particularly important in critically ill patients, in whom the combination of bed rest and catabolic illnesses such as sepsis, multiple trauma, burns, pancreatitis, and acute respiratory distress syndrome (ARDS) hasten the malnutrition, loss of lean body mass, and organ system dysfunction.

The purpose of this chapter is to contrast starvation and stress metabolism with emphasis on protein, carbohydrate, and fat metabolism; review the basic concepts of nutrition support with regard to energy and substrate requirements; discuss routes of nutrition support; provide an overview of organ-specific nutrition and immunonutrition; briefly summarize nutritional assessment and monitoring; and discuss the complications of nutrition support and their prevention.

STARVATION VERSUS STRESS METABOLISM

Starvation is a clinical situation that develops whenever nutrient supply is inadequate to meet nutrient demand. It is characterized by a specific metabolic adaptive response aimed at preserving lean body mass, as well as by decreased energy expenditure, utilization of alternative fuel sources, and reduced protein wasting. During the initial 12 to 24 hours of starvation, glycogen is the primary oxidative fuel source. Thereafter, gluconeogenesis increases temporarily and glucose synthesized from amino acids becomes the

primary fuel source for the production of “obligate” glucose for use by tissues such as the brain and, to some degree, the liver and skeletal muscle. Over time, gluconeogenesis decreases as these organs adapt to ketone bodies as the primary oxidative fuel source, and in the fully adapted starved state, fatty acids, ketones, and glycerol become the primary fuel source in all tissues except the brain and red blood cells. The respiratory quotient (i.e., the ratio of carbon dioxide produced to oxygen consumed) is 0.6 to 0.7 as a result of the use of fat as the primary fuel source. Ultimately, rates of net protein catabolism and ureagenesis are decreased, relative to the fed state, during starvation. From a clinical perspective, it is important to understand that the metabolic response to starvation is reversible with feeding.

Stress metabolism is a generalized response whereby energy and substrate are mobilized to support inflammation, immune function, and tissue repair. It occurs in response to a variety of stimuli such as sepsis, multiple trauma, burns, pancreatitis, bone marrow transplantation, and major surgery. This mobilization of energy and substrate occurs at the expense of lean body mass. It is driven by endocrine hormones such as cortisol, glucagon, and catecholamines, as well as by a multitude of inflammatory mediators. The stress response is often related to some degree of perfusion deficit (shock) and resultant microcirculatory injury. Clinically, the response is characterized by increased energy expenditure and increased oxygen consumption. The stress response is further characterized by hyperglycemia, elevated lactate, and increased urinary nitrogen excretion. The respiratory quotient is often elevated in the range of 0.80 to 0.95 as a result of the use of a mixed oxidative fuel source. Loss of lean body mass occurs more rapidly than with simple starvation because skeletal muscle protein stores become the “fuel” for the stress response. Most important, the malnutrition associated with stress metabolism is less responsive to nutrition support than is starvation metabolism. Reversal of stress-associated malnutrition is dependent not only on the provision of adequate nutrients but also on elimination of the underlying stress response (i.e., control of infection, stabilization of fractures, grafting of burns, or resolution of the inflammatory state). Starvation and stress metabolism are summarized in Table 82.1.

Table 82.1 Starvation Versus Stress Hypermetabolism

Characteristic	Starvation	Hypermetabolism
Energy expenditure	Decreased	Increased
Respiratory quotient	Low (0.7)	High (0.85)
Response to feeding	+++	+
Mediator activation	+	+++
Primary fuels	Fat	Mixed
Gluconeogenesis	+	+++
Proteolysis	+	+++
Protein synthesis	+	++
Ureagenesis/urinary urea nitrogen	+	+++
Ketone formation	++++	+

CARBOHYDRATE METABOLISM IN CRITICAL ILLNESS

Carbohydrate metabolism in critical illness is characterized clinically by hyperglycemia, often described as being due to “insulin resistance” based on increased blood glucose levels in the presence of high circulating levels of insulin. In fact, cellular glucose uptake and oxidation in the critically ill are increased,⁵⁻⁷ and hyperglycemia is associated with increased glucose production, decreased insulin-mediated glucose uptake, and increased non-insulin-mediated glucose uptake.^{5,8}

Glucose production is increased primarily by increased hepatic gluconeogenesis, to a lesser extent by renal gluconeogenesis,⁹ and by increased glycogenolysis. Increased glucose production occurs under the influence of glucagon, catecholamines, and cortisol, with glucagon being the most important stimulant of hepatic gluconeogenesis and epinephrine being the primary stimulant of glycogenolysis.^{10,11} The hormonal changes observed in critical illness appear to be mediated by cytokines in both the central nervous system and peripheral tissues. Interleukin 1 (IL-1) stimulates the release of adrenocorticotrophic hormone, which in turn favors the release of cortisol and glucagon, and tumor necrosis factor (TNF) stimulates increased secretion of glucagon.¹² Gluconeogenic substrates include lactate and alanine, as well as glutamine, glycine, serine, and glycerol. The amino acids used for gluconeogenesis are derived largely from proteolysis in skeletal muscle.

Glucose uptake into cells is regulated by a process of facilitated transport in which a carrier protein promotes the movement of glucose across the cell membrane down its concentration gradient. Three isoforms of this glucose carrier protein (glucose transporter 1 [GLUT-1], GLUT-2, and GLUT-4) are thought to be important in glucose transport.¹³ Non-insulin-mediated glucose uptake is dependent on the GLUT-1 isoform, whereas insulin-mediated glucose transport is dependent on the GLUT-4 isoform. During stress, total body glucose uptake is increased, but largely via non-insulin-mediated pathways.⁸ Non-insulin-mediated glucose uptake is particularly important in the central nervous system and in tissues rich in macrophages and neutrophils (e.g., lung, liver, intestine, spleen, wound), which use glucose for energy and in the process generate the respiratory burst.¹⁴ Inflammatory cytokines may promote the uptake of glucose by increasing the synthesis, plasma membrane concentration, or activity of the glucose transporter.^{15,16} Insulin-mediated glucose transport is suppressed in the liver, heart, and skeletal muscle.^{17,18} Hepatic insulin resistance is characterized by elevated circulating levels of insulin-like growth factor-binding protein-1.^{17,18} The mechanisms of insulin resistance are incompletely understood, although proinflammatory cytokines may alter insulin receptor signaling.^{14,19,20}

The net result of these alterations in carbohydrate metabolism in critical illness is hyperglycemia inasmuch as the liver seems to be unresponsive to high levels of circulating insulin and glucose and continues to synthesize glucose via gluconeogenesis. In other tissues, non-insulin-mediated glucose uptake is enhanced and results in increased glycolytic oxidation to pyruvate and a stoichiometric rise in lactate.^{5,6} Although hyperlactatemia is usually thought of as

being reflective of anaerobic metabolism, it can be indicative of glycolytic flux and the level of metabolic stress when observed in conjunction with elevated pyruvate.⁵

FAT METABOLISM IN CRITICAL ILLNESS

In both starvation and stress metabolism, fat metabolism is characterized by increased lipolysis and decreased lipogenesis as fat stores are mobilized for energy. In the stressed state there is a marked increase in lipolytic activity in adipose tissue as a result of catecholamine-mediated stimulation of β_2 -receptors; cytokines may also participate in this process.^{21,22} Fatty acids are released from adipose tissue in quantities that exceed the amount oxidized, and approximately half of these fatty acids are re-esterified in the liver.²³ In this triglyceride–fatty acid cycle, triglycerides and fatty acids are shunted back and forth between the liver and adipose tissue in an apparently futile pathway.²⁴

Stress fat metabolism is further characterized by increased oxidation of fatty acids of all chain lengths and decreased plasma levels of medium- and long-chain essential fatty acids relative to the quantities of oleic acid. The latter may reflect preferential oxidation of essential fatty acids, suppressed mobilization because of hyperinsulinemia, or conversion of ω -6 fatty acids to inflammatory mediators.

Hypertriglyceridemia is common in critically ill patients, particularly in the presence of multiple organ dysfunction, and results from the combination of increased hepatic triglyceride production and decreased clearance.^{25,26} Hepatic steatosis has classically been attributed to overfeeding because triglycerides are constructed from fatty acids synthesized from excess carbohydrate. This theory has been called into question inasmuch as a substantial proportion of hepatic triglyceride may be synthesized from recycled fatty acids rather than from fatty acids synthesized *de novo* from carbohydrate.²⁷ It is possible that fatty infiltration of the liver reflects a cytokine-mediated defect in triglyceride secretion that represents an organ-specific response to critical illness rather than an adverse effect of carbohydrate overfeeding.^{28,29} Regardless of the immediate source of the fatty acids used in triglyceride synthesis, experience suggests that clinically apparent fatty infiltration of the liver can be prevented by avoiding overfeeding.

Ketonemia is common in starvation, whereas ketogenesis is decreased in stress metabolism.³⁰ Acetoacetate continues to be used as an oxidative fuel source, although the reduction of β -hydroxybutyrate to acetoacetate is impaired.³¹ With the development of multiple organ dysfunction, there is a progressive decrease in the acetoacetate/ β -hydroxybutyrate ratio.³² This alteration in hepatic redox potential reflects a disturbance in the cellular energy charge that may be associated with hepatic mitochondrial damage by toxic oxygen radicals and other inflammatory mediators.³³

PROTEIN METABOLISM IN CRITICAL ILLNESS

Protein synthesis is increased in the stressed state relative to that seen in starvation. Protein breakdown is markedly increased in comparison to the synthetic rate, thereby resulting in net protein catabolism and a rapid decrease in lean body mass.³⁰ There is a net efflux of amino acids from skeletal muscle as protein breakdown via the

ubiquitin-proteasome pathway of protein degradation is accelerated by catecholamines, cortisol, and cytokines.³⁴⁻³⁷

Amino acid uptake by skeletal muscle is impaired despite excess amino acids circulating in the bloodstream early in the course of stress metabolism; the situation deteriorates further as plasma concentrations of specific amino acids such as leucine begin to fall.³⁸ Decreased plasma glutamine is known to have deleterious effects on immune function and gastrointestinal barrier function.^{39,40} Although it has long been thought that the accelerated protein catabolism associated with critical illness is unresponsive to the provision of amino acids or other fuel sources, the fact that muscle amino acid uptake is in part compromised by decreased plasma levels of specific amino acids suggests the possibility that protein catabolism during stress may be attenuated with the provision of appropriate nutrition support.⁴¹

Amino acids mobilized from skeletal muscle are redistributed to other areas of the body to support immune function, wound healing, and tissue repair, as well as for the hepatic synthesis of acute-phase proteins, presumably in an attempt to enhance survival. It has recently been demonstrated that endotoxemia induces significant increases in protein synthesis in the liver, spleen, kidney, jejunum, diaphragm, lung, and skin at the expense of skeletal muscle catabolism.⁴² Amino acids such as alanine, glutamine, glycine, and serine are used as gluconeogenic substrate, and branched-chain amino acids (leucine, isoleucine, and valine) can be used as an oxidative fuel source, particularly in skeletal muscle. The net result of stress protein metabolism is a rapid decrease in lean body mass that exceeds that associated with bed rest or simple starvation, along with increased ureagenesis, azotemia, and increased urinary nitrogen excretion.

INDICATIONS FOR NUTRITION SUPPORT

Nutrition support should be considered once hemorrhage has been controlled, devitalized tissue débrided, fractures stabilized, and the patient resuscitated from shock. Limited data are available regarding the appropriate timing for the institution of nutrition support, although there are suggestions in the literature that early enteral feeding, within 24 to 72 hours of admission, may help decrease postburn and postinjury hypermetabolism and reduce infectious complications. In general, nutrition support should be initiated in any patient who is malnourished on admission to the intensive care unit (ICU), for any patient who is likely to become malnourished during a long and complicated ICU stay, and for any patient who has not eaten for 5 to 7 days.

GOALS OF NUTRITION SUPPORT

The goals of nutrition support in a critically ill patient are to minimize the effects of starvation to provide appropriate doses of macronutrients and micronutrients, to modulate the metabolic processes of the disease, to minimize complications of nutrition support, and to improve outcomes. More specifically, the goals of nutrition support in the critically ill or injured are to provide sufficient calories to meet the energy requirements of the hypermetabolic state while

avoiding the complications associated with overfeeding, provide sufficient protein to attain nitrogen balance or minimize the nitrogen deficit, provide electrolytes to maintain normal levels while taking into account excessive losses or impaired excretion, and provide appropriate vitamins and trace elements with consideration of disease-specific requirements.

NUTRITION SUPPORT IN CRITICAL ILLNESS

CALORIES

In any metabolic state, energy requirements must be met to minimize the use of stored energy reserves and to decrease the loss of lean body mass. In the setting of adapted starvation, the protein-sparing effect of an adequate caloric intake is well recognized; however, in the stressed state, protein catabolism is only partially responsive to caloric intake and continues to a significant degree regardless of caloric intake.^{30,41} Overfeeding is of particular concern in a critically ill patient because it can result in excess carbon dioxide production and ventilator dependence,⁴³ lipogenesis and fatty infiltration of the liver,⁴⁴⁻⁴⁶ and hyperglycemia with its attendant hyperosmolar and infectious complications.^{14,47-49}

The daily caloric requirement depends on total energy expenditure (TEE), which is the sum of basal energy expenditure (BEE), diet-induced thermogenesis (DIT), and activity energy expenditure (AEE). BEE is the caloric expenditure of a person in the recumbent position who has fasted for at least 10 hours. DIT is the energy expended to perform all aspects of food consumption, including eating and hydrolysis and absorption of nutrients, and may account for 15% to 40% of TEE. Resting energy expenditure (REE) is the energy expenditure of a recumbent person who is not fasting and is the sum of BEE and DIT. These relationships can be expressed by the following equations:

$$\text{REE} = \text{BEE} + \text{DIT}$$

$$\text{TEE} = \text{REE} + \text{AEE}$$

Caloric requirement can be estimated by using a number of formulas or can be measured with indirect calorimetry. Most commonly, BEE is estimated with the Harris-Benedict equations, which are based on sex, age, height, and weight and then multiplied by stress and activity factors to estimate caloric requirement. The Harris-Benedict equations are as follows:

For males:

$$\text{BEE} = 66.42 + (13.75 \times \text{Wt [kg]}) + (5.0 \times \text{Ht [cm]}) - (6.77 \times \text{Age [yr]})$$

For females:

$$\text{BEE} = 655.10 + (9.65 \times \text{Wt [kg]}) + 1.85 \times \text{Ht [cm]} - (4.68 \times \text{Age [yr]})$$

Classically, REE is then estimated by multiplying the calculated BEE by a stress factor ranging from 1.0 in a stable, mechanically ventilated patient to 2.0 in a patient with a 50% total body surface area burn. Stress factors for patients

with multiple trauma or sepsis fall somewhere between the two extremes. TEE is estimated by multiplying REE by an activity factor of 1.2 to 1.3 for ambulatory patients. The caloric requirement is decreased to varying degrees (6% to 30%) in mechanically ventilated patients receiving narcotics or sedatives and is reduced by as much as 33% in chemically paralyzed patients.⁵⁰ In nonventilated postoperative patients or in patients with decreased lung compliance, energy expenditure related to the work of breathing may increase. Although estimation of energy expenditure is relatively accurate in healthy people, it is much less reliable in critically ill patients because of the heterogeneity of the metabolic response and variations in sedation, work of breathing, and physical activity. Most critically ill patients should receive calories to supply 100% to 120% of calculated BEE. Estimation of energy expenditure in obese patients is particularly difficult. If indirect calorimetry is unavailable, the provision of calories should be based upon body mass index (BMI) and ideal body weight rather than on obesity adjusted body weight.⁵¹

Indirect calorimetry can be used to measure REE and does not require the addition of estimated stress factors. REE is based on measured oxygen consumption and carbon dioxide production and is calculated according to the Weir equation:

$$\text{REE} = (3.94 \times \text{VO}_2) + (1.1 \times (\text{VCO}_2))$$

where VO_2 = oxygen consumption and VCO_2 = carbon dioxide production.

Even when not used routinely, indirect calorimetry can still be helpful in assessing the energy needs of obese patients, to rule out overfeeding in patients with seemingly excessive ventilatory demands, in severely malnourished patients, and in patients with apparently high levels of metabolic stress.

In general, critically ill patients should receive 25 to 30 kcal/kg/day, with sedated mechanically ventilated patients receiving closer to 25 kcal/kg/day. Chemically paralyzed patients generally require 20 kcal/kg/day.⁵² In obese patients, hypocaloric feeding may induce some degree of weight loss and improve insulin sensitivity and may decrease ventilator days and length of ICU stay.⁵² In patients with a BMI greater than 30, calories should not exceed 60% to 70% of target energy requirements or 11 to 14 kcal/kg actual body weight per day or 22 to 25 kcal/kg ideal body weight per day.⁵¹

CARBOHYDRATE

Carbohydrate is usually the primary source of calories in human beings. The maximal rate of glucose oxidation is approximately 5 mg/kg/minute, or 7.2 g/kg/day.⁵³ In stressed patients, part of this maximally tolerated glucose load will be provided by glucose synthesized endogenously from amino acids via gluconeogenesis. In a severely hypermetabolic patient, gluconeogenesis may provide as much as 4 mg/kg/minute of glucose⁵⁴ and result in significant hyperglycemia when large exogenous glucose loads are administered. Insulin tends to be ineffective in controlling this hyperglycemia, in part because glucose oxidation may already be maximal, endogenous insulin levels are already high, and insulin-mediated glucose uptake in the liver and

Table 82.2 Nutrition Support in a Hypermetabolic Patient

Nutrient	General Recommendation
Total calories	25-30 kcal/kg/day OR $BEE \times 1.2-2.0$ OR REE by IDC
Glucose	5 g/kg/day OR 20 kcal/kg/day OR 60-70% of calories
Fat	15-40% of calories OR Less than 1 g/kg/day
Amino acids or protein	1.2-2.0 g/kg/day
Trace elements and vitamins	RDA
Electrolytes	Maintain normal levels

BEE, basal energy expenditure; IDC, indirect calorimetry; RDA, recommended dietary allowance; REE, resting energy expenditure.

other tissues is suppressed in a septic and hypermetabolic patient.^{17,18} Complications of excess glucose administration include hyperglycemia and its attendant hyperosmolar/infectious complications, excess carbon dioxide production and ventilator dependence, and hepatic steatosis. In general, glucose should initially be provided at a rate of 5 g/kg/day or approximately 20 kcal/kg/day. Carbohydrate should generally constitute 60% to 70% of nonprotein calories in a hypermetabolic patient (Table 82.2).

FAT

In a hypermetabolic patient, fat should constitute 15% to 40% of daily caloric intake, both to prevent essential fatty acid deficiency and to meet caloric needs in the face of a fixed capacity to oxidize glucose. In the starved state, as little as 2% to 5% of calories can be provided as fat, primarily to prevent essential fatty acid deficiency. Substituting lipid calories for carbohydrate calories can reduce carbon dioxide production, although avoiding excess calories in general is probably most important in minimizing carbon dioxide production and ventilator dependence. Complications of excess lipid administration, particularly when given parenterally, include hyperlipemia, immunosuppression, and hypoxemia as a result of both impaired oxygen diffusion and ventilation-perfusion mismatching. In general, a hypermetabolic patient should receive 15% to 40% of calories as fat, not to exceed 1.0 to 1.5 g/kg/day (see Table 82.2).⁵⁵

PROTEIN

Protein needs in a hypermetabolic patient are increased in comparison to those in a patient with simple starvation. Protein catabolism in a stressed patient has long been thought to be unresponsive to protein or amino acid

administration or glucose infusion,⁵⁶ and attainment of nitrogen balance is thought to depend largely on the support of stress protein synthesis.⁴¹ However, recent evidence suggests that protein catabolism may be attenuated by the provision of appropriate nutrition support.⁴² Regardless of the specific mechanisms involved, lean body mass decreases during catabolic illness because of bed rest and inactivity. Amino acids are redistributed from skeletal muscle to support hepatic protein synthesis, the cellular inflammatory response, and gluconeogenesis and are used as oxidative fuel sources. The critically ill or injured patient may require 1.2 to 2.0 g/kg/day to promote nitrogen balance or at least minimize the nitrogen deficit. With the exceptions noted later, the provision of more than 2.0 g/kg/day of protein rarely promotes nitrogen balance and usually results simply in increased urinary nitrogen excretion (see Table 82.2).

To meet the protein requirements of the stressed state and at the same time avoid excess calories and the attendant complications, an injured or septic patient may require nutrition support with a nonprotein calorie-to-nitrogen ratio of 80:1 or 100:1, as compared with a patient with starvation metabolism, who may tolerate a nonprotein calorie-to-nitrogen ratio of 150:1 or higher. The higher protein needs of a patient with catabolic illness can be met with custom-compounded total parenteral nutrition (TPN) or with numerous commercially available enteral formulas specifically designed for such patients (Table 82.3).

In summary, most critically ill patients should receive 1.2 to 2.0 g/kg/day of protein. Obese patients with BMI 30 to 40 should receive at least 2.0 g/kg/day of protein and patients with BMI greater than 40 should receive at least 2.5 g/kg/day in conjunction with hypocaloric feeding.⁵¹ Critically ill patients with renal failure should generally receive 1.25 to 1.75 g/kg/day and those requiring continuous renal replacement therapy (CRRT) may require up to 2.5 g/kg/day.⁵¹

ELECTROLYTES, VITAMINS, AND TRACE ELEMENTS

Fluid and electrolytes should be provided to maintain adequate urine output and normal serum electrolyte levels. Typical daily electrolyte requirements include sodium 60 to 100 mEq/day, potassium 60 to 100 mEq/day, magnesium 10 to 20 mEq/day, calcium 10 to 15 mEq/day, chloride 80 to 120 mEq/day, and phosphorus 20 to 30 mmol/day.⁵⁷ Intravenous amino acid formulations contain acetate, but additional acetate can be added in the setting of metabolic acidosis. Particular attention should be paid to the intracellular electrolytes (potassium, phosphorus, and magnesium), which are required for attainment of nitrogen balance⁵⁸ and serum levels of which can fall precipitously when nutrition support is initiated.

The requirements for vitamins and trace elements in critical illness are largely unknown, and in general the recommended dietary allowance (RDA) for both should be provided. Antioxidant vitamins (including vitamins E and ascorbic acid) and trace minerals (including zinc, copper, and particularly selenium) may improve outcome in burns, in trauma, and in critically ill patients requiring mechanical

Table 82.3 Enteral Nutrition Formulas

Type	General Information	Sample Formulas	Concentration (kcal/mL)	Nonprotein Calorie: Nitrogen				
				Osmolality	Ratio	Protein (g/1000 kcal)	Carbohydrate (% kcal)	Fat (% kcal)

BCAAs, branched-chain amino acids; GI, gastrointestinal; MCT, medium-chain triglyceride.

ventilation⁵⁹ and should be provided to all critically ill patients receiving specialized nutrition support.⁵¹ Patients with prolonged diarrhea or large burns or those undergoing dialysis have increased trace element loss and vitamin requirements, and deficiencies can develop if intake is inadequate. Initial limitation of trace elements should be considered in patients with renal failure. Routine supplementation of vitamins is necessary in patients receiving TPN. Typically, one ampule of a standard multivitamin preparation is added to TPN daily. Vitamin K, which is light sensitive, must be added separately in a light-impermeable bag or given by another route once or twice weekly. Excessive doses of vitamin C should be avoided in renal failure because of the accumulation of oxalate. Vitamin A accumulates and should not be supplemented beyond the RDA.⁶⁰

ROUTE AND TIMING OF ADMINISTRATION

Nutrition support can be delivered enterally (via the gastrointestinal tract) or parenterally (via the intravenous route). The preferred route has been the subject of considerable controversy during the past 40 years.

Both routes have advantages and disadvantages, and nitrogen balance can be achieved by either route. TPN does not require an intact or functioning gastrointestinal tract, it is convenient to use, and its use virtually guarantees that the nutrients prescribed will be administered and that these nutrients will appear in the bloodstream. Disadvantages of parenteral nutrition include cost, procedure (central venous catheter)-related complications, an increased likelihood of metabolic complications, including hyperglycemia, and an increased risk of infectious complications. Enteral nutrition is much less expensive, is more physiologic, is associated with fewer metabolic complications such as electrolyte abnormalities and hyperglycemia, and stimulates gut function and preserves mucosal integrity and barrier function better than parenteral nutrition does. Disadvantages of enteral nutrition include the requirement for an intact and functioning gastrointestinal tract, procedure (feeding tube placement)-related complications, pulmonary aspiration, malabsorption, feeding intolerance (pain, vomiting, bloating, diarrhea), and as a result, an inability to deliver the entire nutrient prescription.

The gastrointestinal tract is a major interface between the host and the environment and not only regulates the ingestion and absorption of nutrients but is also responsible for defending the host against noxious microorganisms and toxins.⁶¹ Malnutrition impairs gastrointestinal barrier function,⁶² as does the lack of luminal nutrients independent of general nutritional status.^{63,64} Enteral nutrition has been shown to promote mucosal growth, improve absorptive capacity, alter digestive enzyme production, improve gut mucosal weight, generate DNA and protein synthesis, and improve the efficiency of nutrient utilization.⁶⁵ Enteral nutrition stimulates intestinal contractility; the release of trophic substances such as bile salts, gastrin, and motilin; and the release of secretory IgA.^{65a-65d} Enteral nutrition supports commensal bacteria, which in turn degrade bacterial toxins and prevent gut colonization by pathogenic organisms.^{65a,65e} Further, enteral nutrition stimulates gut

blood flow and supports gut-associated lymphoid tissue (GALT).^{65a-65d} Enteral nutrition supports the processing of naïve CD4 helper lymphocytes by exposure to bacterial antigens in the gut. These IgA-producing lymphocytes then migrate to distant organs such as lungs, liver, and kidneys, where they form mucosal-associated lymphoid tissue (MALT) and produce secretory IgA.^{65a-65d} T_H2 CD4 helper lymphocytes, the proliferation of which are stimulated by feeding, enter the circulation and have an anti-inflammatory effect.^{65a,65f,65g} Enteral nutrients stimulate the proliferation of T_H1 and T_H3 lymphocytes,^{65f} which in turn release transforming growth factor- β (TGF- β), resulting in a further down-regulatory or anti-inflammatory effect.^{65a,65f}

Several randomized prospective trials in a variety of critically ill patient populations, including trauma, burns, head injury, major surgery, and acute pancreatitis, have documented the benefits of enteral compared to parenteral nutrition.⁶⁶⁻⁷¹ Few studies show a beneficial effect on mortality rate, but most demonstrate reduced infectious morbidity, primarily pneumonia and central line infections. In trauma patients, enteral nutrition has been associated with a reduction in abdominal abscesses.⁶⁷ Further, enteral nutrition has been associated with decreased length of hospital stay,⁶⁹ and in head injury patients, return of cognitive function.⁷¹ Several meta-analyses comparing enteral to parenteral nutrition have shown significant reductions in infectious complications with the use of enteral nutrition.⁷²⁻⁷⁵

Parenteral nutrition, although able to maintain overall nutritional status, does not offer the benefits related to gut mucosal integrity and immune function mentioned earlier. Whether this is the primary reason for the increased infection risk associated with parenteral nutrition is less clear. In several of the studies mentioned in previous paragraphs, many of the patients managed with parenteral nutrition received significantly more calories and had a higher incidence of hyperglycemia⁷³ than did their enterally fed counterparts. In a study in which parenterally fed patients had a higher incidence of sepsis, twice as many patients receiving parenteral nutrition had hyperglycemia as enterally fed patients.⁷⁰ More recently, in a large prospective trial comparing tight glucose control with standard glucose control, patients with tight glucose control had significantly lower rates of morbidity, infectious complications, and mortality.⁴⁹ Further analysis of these data revealed that when glucose was tightly controlled, there was no difference in infection when patients were nourished parenterally rather than enterally.⁷⁷ These data suggest that control of hyperglycemia may be as important as the route of nutrition in minimizing infectious complications.

In summary, because it is less costly and associated with fewer metabolic complications and a lower incidence of infection, the enteral route continues to be the recommended route for nutrition support.⁵¹ That said, in as many as 15% of critically ill patients, enteral nutrition is either contraindicated or not tolerated, and parenteral nutrition remains a viable option, particularly when overfeeding is avoided and hyperglycemia is controlled.⁵¹

The timing for the initiation of nutrition support in critically ill patients has also been controversial. It has been suggested that enteral nutrition started early (within 24 to 72 hours of admission or the onset of the hypermetabolic insult) is associated with less gut permeability, release of

inflammatory cytokines, and reduced systemic endotoxemia.⁶⁹ Further, the accumulation of an energy deficit early in the course of an ICU admission has been significantly associated with the occurrence of ARDS, renal failure, pressure ulcers, and the need for surgery^{77a} and with longer ICU length of stay and more days of mechanical ventilation.^{77,78} In a meta-analysis by Heyland and associates, early enteral nutrition was associated with a trend toward reduced infectious morbidity and mortality rates.⁶⁹ A second meta-analysis by Marik and Zaloga demonstrated significant reductions in infectious morbidity and hospital length of stay with early enteral nutrition as compared to delayed feedings.⁷⁷ In patients who are hemodynamically stable, it is recommended that enteral nutrition be started within 48 hours of admission.⁷⁶

The early use of TPN to supplement enteral nutrition and thus prevent a caloric deficit has been controversial.^{69,71,78} In a recent prospective, randomized, multi-institutional trial 2312 patients were randomized to initiation of parenteral nutrition to supplement insufficient enteral nutrition within 48 hours of ICU admission (early initiation group) and compared to 2328 patients randomized to receive supplementary parenteral nutrition no earlier than 8 days after ICU admission (late initiation group). All patients received early enteral nutrition by protocol and had insulin infused to maintain normoglycemia. The late initiation group was slightly more likely to be discharged alive from the ICU and from the hospital without evidence of decreased functional status. Further, patients in the late initiation group had significantly fewer infections, a significant reduction in the proportion of patients requiring more than 2 days of mechanical ventilation, a significant median reduction of 3 days in the duration of renal replacement therapy, and a mean reduction in health care costs of approximately \$1600. These patients were considered to be at nutritional risk but not malnourished on admission based on BMI.⁷⁹ These results suggest that early parenteral nutrition, even when used to supplement enteral nutrition, may be harmful and should be avoided unless the patient is chronically malnourished.

TYPES OF NUTRITIONAL FORMULAS

Parenteral nutrition is most commonly administered as a three-in-one solution of dextrose, lipid, and amino acids. TPN order forms typically allow the physician to order “standard” or custom solutions, fluid-restricted solutions, and in some cases, disease-specific solutions such as renal failure or hepatic failure solutions. Electrolytes can usually be added in standard stock concentrations or individually. Vitamins and trace elements are generally added in standard quantities but can be supplemented. H₂ blockers for stress ulcer prophylaxis and regular insulin can also be added.

Enteral formulas are usually premixed with a fixed nonprotein calorie-to-nitrogen ratio, and the needs of a specific patient are generally met by changing the formula. Protein and carbohydrate supplements can be added at the bedside to alter premixed formulas. Enteral formulas can be classified numerous ways, including the form in which protein is provided (e.g., intact protein, hydrolyzed protein

[chemically defined or peptide], or crystalline amino acids [elemental]), the quantity of protein contained, the caloric density of the formula, and the disease state for which they were designed. Examples of different formulas are shown in Table 82.3. More detailed information is available elsewhere.⁸⁰

Intact protein solutions contain protein as caseinate or soy isolate-based products that are lactose-free, gluten-free, and low in residue. Such solutions contain 45% to 60% of calories as carbohydrate (oligosaccharides), 20% to 35% of calories as long-chain fats (e.g., linoleic acid), and 15% to 20% of calories as protein. Intact formulas are usually isotonic and may contain 1 to 2 kcal/mL of solution. Some formulas contain fiber as a means to improve diarrhea or glycemic control. Hydrolyzed formulas provide protein as peptides or amino acids, are generally low in fat, and are designed for patients with gut dysfunction or malabsorption.⁸¹ Elemental solutions contain protein exclusively as amino acids and are intended for similar indications. Controlled studies comparing hydrolyzed or elemental formulas with intact formulas have not demonstrated improved tolerance or outcomes.

High-protein formulas contain more than 45 g protein per 1000 kcal and are designed for patients with increased protein needs, such as patients with catabolic illness.

Calorie-dense formulas are designed for patients in whom fluid restriction is required. They are generally relatively low in protein and not ideal for a stressed patient.

ORGAN-SPECIFIC ENTERAL FORMULAS

Organ-specific formulas are products designed to meet the nutritional requirements of patients with specific organ failures. None has been consistently shown to improve outcomes when compared with conventional formulas.

Pulmonary failure formulas are designed for patients with acute respiratory failure associated with chronic lung disease. They contain at least 50% of calories as fat and thus reduce CO₂ production and decrease the work of breathing relative to high-carbohydrate formulas. Few data suggest a benefit with specific pulmonary formulas, and avoiding overfeeding is more important in reducing ventilatory demand.^{82,75}

Hepatic failure formulas were developed for patients with encephalopathy. They contain high concentrations of branched-chain amino acids and reduced concentrations of aromatic amino acids. Although these solutions have been shown to correct the abnormal amino acid profile characteristic of patients with liver failure,^{83,84} it is less clear that they actually treat hepatic encephalopathy.⁸⁴ Hepatic failure formulas should be reserved for the rare encephalopathic patient who is refractory to lactulose and luminal antibiotics.⁵¹

Renal failure formulas have reduced concentrations of electrolytes and decreased protein content to minimize nitrogenous waste in patients with renal failure. Patients with acute renal failure frequently have associated catabolic illness and as a result need more protein rather than less. Although these formulas may be useful in patients with electrolyte abnormalities not yet being dialyzed, they are inappropriate for patients with catabolic illness who are undergoing dialysis and particularly CRRT.

IMMUNOMODULATING ENTERAL FORMULAS

Immunomodulating enteral formulas are supplemented with various combinations of specific nutrients, arginine, ω -3 polyunsaturated fatty acids, nucleotides, glutamine, and antioxidants aimed at improving immune function and reducing inflammation in critically ill patients.

Arginine is a nonessential amino acid that has both beneficial and deleterious effects. It is a secretagogue for anabolic hormones, supports T-cell function, detoxifies ammonia, and supports wound healing via metabolism to polyamine and proline.^{85,86} An arginine deficiency may develop after trauma or major surgery that is mediated by pathologic release of arginase from granulocytes.⁸⁶⁻⁸⁸ Arginine deficiency impairs the immune response, which may result in increased infections and in impaired wound healing.^{86,87,89} Arginine is a precursor for the synthesis of nitric oxide, which in turn is a modulator of hepatic protein synthesis and vascular tone. This nitric oxide-induced vasodilation may be beneficial in some circumstances but in the setting of severe sepsis and hypotension may aggravate hemodynamic collapse. Further, nitric oxide is metabolized to peroxynitrite,^{86,90} which is a potent oxidizing and nitrating agent that may damage mitochondria, increase gut barrier permeability, and promote organ dysfunction.^{86,90-95}

Omega-3 fatty acids are incorporated into the phospholipid fraction of cell membranes and converted to trienoic prostaglandins and pentaenoic leukotrienes, which are less “inflammatory” than their ω -6 counterparts. Omega-3 fatty acids have been shown to decrease prostaglandin E₂, TNF, and IL-1 production in rat Kupffer cells⁹⁶ and alter TNF and IL-1 production in human monocytes.⁹⁷ Furthermore, ω -3 fats have been shown to be beneficial in animal models of chronic inflammation and in humans with psoriasis⁹⁸ and rheumatoid arthritis.⁹⁹

Glutamine is an important fuel for enterocytes and cells of the immune system. Considered a nonessential amino acid, glutamine may become conditionally essential when skeletal muscle stores and plasma levels become depleted during catabolic illness, thereby resulting in adverse effects on gut barrier and immune function.¹⁰⁰⁻¹⁰² Glutamine has been shown to improve nitrogen balance and decrease bacterial translocation in animals.¹⁰³⁻¹⁰⁵ It also promotes the synthesis of glutathione, an important antioxidant. A meta-analysis of 14 randomized trials in which glutamine-supplemented nutrition was compared with standard nutrition demonstrated reduced infectious morbidity and mortality rates with glutamine supplementation, particularly in parenterally nourished surgical patients.¹⁰⁶ Unfortunately, glutamine dipeptide, which is the optimal form for parenteral administration due to stability and the minimal added volume required for infusion, is not currently available in the United States.⁸⁶

Antioxidants such as vitamins A, E, and C; selenium; and N-acetylcysteine offer the potential to reduce oxidant injury but have not been studied individually in critically ill patients in terms of clinical outcomes.¹⁰⁷

Numerous studies comparing immunity-enhancing enteral nutrition with conventional nutrition have produced contradictory results. In a 2001 meta-analysis of 22 studies (2419 patients) in which enteral nutrition supplemented with various combinations of arginine, ω -3 fatty acids,

glutamine, and nucleotides was compared with conventional enteral nutrition, the supplemented patients had decreased infectious morbidity but no difference in mortality rates when compared with patients receiving the control diet.¹⁰⁸ The majority of studies demonstrating benefit involved elective surgery patients and not critically ill patients. In the subsequently published and largest (597 patients) randomized trial to date, immunonutrition had no benefit in terms of infectious morbidity, length of hospital stay, number of ventilator days, or mortality rate.¹⁰⁹ In retrospect, it appears that a number of factors may have been responsible for the conflicting results mentioned earlier. First, there was considerable heterogeneity in the patient populations studied (major elective surgery, burns, trauma, sepsis, and ARDS). Second, the immunomodulating enteral formulas studied contained varying combinations of arginine, ω -3 polyunsaturated fatty acids (fish oil), glutamine, and antioxidants. These differences were addressed in a 2008 meta-analysis of 24 studies by Marik and Zaloga in which studies were analyzed by patient type (ICU, burns, and trauma) and by the combination of immunomodulating nutrients in the subject study formula (fish oil, arginine, glutamine, fish oil plus arginine, fish oil plus arginine plus glutamine).¹¹⁰ All enteral formulas contained antioxidants, primarily selenium, though in varying doses, and could not be studied separately. Overall, the immunomodulating diets had no effect on mortality rate but did demonstrate significant reductions in secondary infections. Mortality rates, infections, and length of stay were significantly reduced only in ICU patients with sepsis, systemic inflammatory response syndrome (SIRS), and ARDS receiving a formula supplemented with fish oil alone.¹¹¹⁻¹¹³ Infection and length of stay were reduced in the 13 ICU studies, but this effect disappeared when the three fish oil studies were excluded.¹¹⁰ It appears that arginine, perhaps due to the preceding mechanisms, counteracts the beneficial effects of fish oil in trauma and ICU patients with sepsis/SIRS.

Currently, the 2009 guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient, published jointly by the Society of Critical Care Medicine and the American Society for Parenteral and Enteral Nutrition, recommend the use of an immunomodulating enteral formula supplemented with fish oil and antioxidants for patients with acute lung injury/ARDS.⁷⁵ Further, these guidelines recommend enteral formulas supplemented with arginine for patients with major surgery, burns, and trauma, but emphasize that such formulas may be harmful in severe sepsis. Finally, the guidelines describe glutamine as possibly beneficial in trauma and burns.⁵¹

NUTRITIONAL ASSESSMENT AND MONITORING

The history and physical examination remain the mainstay of nutritional assessment, although they are perhaps more useful in the ambulatory setting or in patients with chronic malnutrition.¹¹⁴ Pertinent historical information includes height and weight, a history of recent weight change, genetic background, recent nutritional intake, and a history of disease that might affect nutrient intake, absorption, or tolerance. The physical examination might, on occasion,

Table 82.4 Selected Vitamin Deficiencies

Vitamin	Function	Signs of Deficiency
Niacin (vitamin B ₃)	Component of the coenzymes NAD and NADP, which catalyze oxidation-reduction reactions and play a role in the oxidative catabolism of carbohydrates, proteins, and lipids and the biosynthesis of fatty acids	Pellagra, dermatitis, headaches, loss of memory, dementia, glossitis, diarrhea
Folate (vitamin B ₉) Cyanocobalamin (vitamin B ₁₂)	Transfer of single-carbon units; DNA synthesis Maintains normal folate metabolism; coenzyme in reactions involving isomerizations and reductions; participates in the metabolism of fat, carbohydrate, and protein and in myelin synthesis	Megaloblastic anemia, diarrhea, glossitis Pernicious anemia, glossitis, peripheral neuropathy, spinal cord degeneration
Thiamine	Carbohydrate metabolism coenzyme in oxidative decarboxylation	Paresthesias, impaired memory, nystagmus, congestive heart failure, Wernicke-Korsakoff syndrome
Riboflavin (vitamin B ₂)	Electronic transport as flavin nucleotides	Mucositis, dermatitis, cheilosis, vascularization of the cornea, photophobia, decreased vision, lacrimation, impaired wound healing
Pyridoxine (vitamin B ₆) Pantothenic acid	Coenzyme in transformations of amino acids Precursor of coenzyme A (Krebs cycle)	Neuritis, dermatitis, convulsions Headache, fatigue, malaise, insomnia, vomiting, abdominal cramps
Biotin	Coenzyme for carboxylation reactions	As with other B vitamins (normally synthesized and absorbed from gut)
Ascorbic acid (vitamin C)	Reducing agent, wound healing, integrity of blood vessels, folate metabolism	Enlargement and keratosis of hair follicles, impaired wound healing, anemia, ecchymosis, lethargy, depression, bleeding
Vitamin A	Normal vision, mucopolysaccharide synthesis, protease release, entry of macrophages and leukocytes into an acute wound, immune stimulation, mucosal integrity	Dermatitis, keratomalacia, xerophthalmia, night blindness
Vitamin D	Calcium and phosphorus homeostasis	Rickets, osteomalacia
Vitamin E	Antioxidant	Hemolysis
Vitamin K	Clotting factors II, VII, IX, X	Bleeding

NAD, nicotinamide-adenine dinucleotide; NADP, nicotinamide-adenine dinucleotide phosphate.

demonstrate abnormal end-organ function that reflects malnutrition, but more commonly it is useful for the assessment of body mass and detection of specific nutrient deficiencies. Signs and symptoms of selected vitamin and mineral deficiencies are presented in [Tables 82.4 and 82.5](#).

Anthropometric measurements such as triceps skinfold thickness (SFT), midarm circumference (MAC), and arm muscle area, which is derived from SFT and MAC, can be used to estimate fat mass and lean body mass.¹¹⁵ Although serial measurements may be useful in certain patients over long periods, SFT measurements are less reliable in the elderly because of changes in fat distribution and skin compressibility associated with aging^{115,116} and are inaccurate in patients with peripheral edema.¹¹⁷ In general, these measurements are not practical for nutritional monitoring in a recumbent, critically ill patient.¹¹⁸

Visceral protein levels have long been used in nutritional assessment and monitoring and can be useful in the appropriate clinical setting. They are affected by a number of variables other than nutritional status, such as hydration state and gastrointestinal and urinary losses, and must therefore be used cautiously in a critically ill patient.

Albumin is contained in a large body pool (4 to 5 g/kg) and has a half-life of 20 days, so it is insensitive to acute changes and responds slowly to nutritional therapy. Serum albumin levels are decreased in nephrotic syndrome, enteropathies, hepatic failure, and dialysis (particularly peritoneal dialysis), as well as in the setting of acute volume expansion. Levels may be increased in the presence of dehydration, hypercortisolemia, and anabolic hormones such as insulin, growth hormone, and estrogen. Although serum albumin levels are useful in predicting surgical mortality rate and monitoring nutritional status over the long term, they are much less useful in monitoring a critically ill patient.¹¹⁹

Transferrin is contained in a smaller body pool and has a shorter half-life than albumin does (8 to 10 days), so it is a more sensitive indicator of nutritional status. It is subject to the same influences as mentioned for albumin and, in addition, is affected inversely by serum iron levels.¹²⁰

Retinol-binding protein is a specific carrier involved in vitamin A transport and is linked with thyroxine-binding prealbumin in a constant molar ratio.¹²¹ It has a 12-hour

Table 82.5 Selected Mineral Deficiencies

Trace Element	Function	Signs of Deficiency
Chromium	Glucose tolerance; possible role in maintenance of normal serum lipid levels	Elevated serum lipids, insulin-resistant glucose intolerance
Copper	Metalloenzyme biochemical processes, component of ceruloplasmin, connective tissue metabolism, melanin formation	Anemia, neutropenia, leukopenia, depigmentation of skin
Iron	Constituent of hemoglobin, myoglobin, and the cytochrome enzymes	Microcytic hypochromic anemia, fatigue, faulty digestion, decreased serum iron
Zinc	Essential for the function of many enzymes and a component of lipid, protein, carbohydrate, and nucleic acid metabolism; cell replication and connective tissue synthesis	Dermatitis; impaired wound healing; alopecia; depressed cell-mediated immunity, taste acuity, and dark adaptation; sexual retardation; depressed visceral protein status
Cobalt	Biologic methylation	Pernicious anemia, methylmalonic aciduria
Manganese	Oxidative phosphorylation, fatty acid metabolism, protein and mucopolysaccharide synthesis	Growth retardation, bony abnormalities, central nervous system dysfunction

half-life and is sensitive to synthesis and utilization rates. Levels rise in patients with renal disease¹²² and with excess vitamin A administration and are reduced in patients with liver disease, cystic fibrosis, hyperthyroidism, and vitamin A deficiency.

Transthyretin (thyroxine-binding prealbumin) is involved in the transport of thyroid hormone and is a carrier for retinol-binding protein. It has a small body pool and a short half-life (2 to 3 days) and as such may be a sensitive indicator of nutritional status.^{123,124} Levels are affected by the same variables that affect albumin and transferrin. Levels are low in patients with hyperthyroidism, cystic fibrosis, chronic illness, and acute stress. Because of its short half-life and ease of measurement, transthyretin is the visceral protein of choice for nutritional assessment and monitoring, although its use in a critically ill patient is controversial. During catabolic illness, hepatic protein synthesis is reprioritized, under the influence of cytokines, with increased synthesis of acute-phase reactant proteins and decreased synthesis of visceral proteins.¹²⁵⁻¹²⁷ Transthyretin levels fall early in the course of catabolic illness and rise with the subsequent decrease in acute-phase reactant proteins as a result of reversal of the reprioritized hepatic protein synthesis. The association of this response with specific nutrients,¹²⁸⁻¹³¹ nitrogen balance,^{52,132-135} and outcomes^{71,134,136} has been variable. Whether transthyretin levels are reflective of appropriate nutrition support or simply a reflection of the course and severity of the inflammatory response is unclear. An initial transthyretin level lower than 50 mg/L or failure to increase by 40 mg/L per week has been associated with a poor prognosis.¹²⁴

In general, because visceral protein levels are affected by a variety of non-nutritional factors, they are not recommended for the monitoring of nutritional status in critically ill patients.⁵¹

Nitrogen balance is the nutritional parameter most consistently associated with improved outcomes, and nitrogen balance studies are used routinely in many ICUs to monitor nutrition support. Ideally, positive nitrogen balance is the goal, but minimizing the nitrogen deficit in a critically ill patient is probably more realistic when one considers the fact that proteolysis in the skeletal muscle compartment,

which constitutes 70% of body protein stores, is likely to exceed protein synthesis related to the inflammatory response and wound healing, simply because of the size of the compartments involved. Nitrogen balance is calculated as follows:

$$\text{Nitrogen balance (g)} = \text{Nitrogen intake (g)} - \text{Nitrogen output (g)}$$

$$\text{Nitrogen intake (g)} = \text{Protein or amino acid intake (g)} / 6.25$$

$$\text{Nitrogen output (g)} = \text{Urinary nitrogen losses (g)} + 2 \text{ g (stool and skin losses)}$$

Urinary nitrogen consists of several components, including urea, creatinine, uric acid, ammonia, and amino acids. In health, urea constitutes 90% of urinary nitrogen, whereas in catabolic states, urea may represent as little as 70% of urinary nitrogen. Measurement of total urinary nitrogen (TUN) is complex and not done in most hospitals, whereas urinary urea nitrogen (UUN) is measured routinely. When UUN is used in the calculation of urinary nitrogen excretion, an additional 20% of the UUN is added to account for nonurea nitrogen losses. In the absence of abnormal stool or skin losses, nitrogen output is calculated as

$$\text{Nitrogen output (g)} = \text{TUN (g/24 hours)} + 2 \text{ g (stool and skin losses)}$$

or

$$\text{Nitrogen output (g)} = \text{UUN (g/24 hours)} + 20\% \text{ UUN} + 2 \text{ g (stool and skin losses)}$$

Classically, measurement of urinary nitrogen excretion involves a 24-hour urine collection, but recent evidence suggests that a carefully collected 12- or even 6-hour urine collection can be obtained and extrapolated to a 24-hour period.¹³⁷ Nitrogen balance is usually calculated weekly.

Numerous techniques for assessment and monitoring of energy balance have been studied, including continuous whole-body calorimetry,¹³⁸ the doubly labeled water technique,¹³⁸ and nuclear magnetic resonance spectroscopy using ³¹P,¹³⁹ but no method is ideal. Though potentially useful, these methods are either cumbersome, expensive, or impractical for use in critically ill patients.

Indirect calorimetry is used to determine the heat produced by oxidative processes by measuring oxygen consumption and carbon dioxide production, which are then used to calculate REE via the abbreviated Weir equation.^{140,141} Indirect calorimetry is widely used at the bedside, convenient, relatively inexpensive, and accurately estimates REE when compared with standard predictive formulas.¹⁴²⁻¹⁴⁸ Indirect calorimetry is performed on patients at rest and therefore does not account for energy expenditure during periods of activity. Many clinicians will increase caloric input by 20% to 25% above measured REE to account for physical activity, particularly in patients who are agitated, ambulatory, or involved in intense physical therapy.¹⁴⁹⁻¹⁵¹

In addition to the nutrition-specific monitoring techniques mentioned, the usual laboratory values should be monitored for fluid and electrolyte composition, hepatic function, infection, and any coagulopathy that might reflect vitamin K deficiency. In a critically ill patient, serum electrolytes (Na^+ , K^+ , Cl^- , and HCO_3^-) should be determined

daily and as needed. Special attention should be paid to the intracellular electrolytes (K^+ , Mg^{2+} , and PO_4^{2-}), which are required for the attainment of nitrogen balance⁷³ and can fall precipitously when nutrition support, particularly glucose, is initiated. Rapid uptake into cells can result in dangerously low serum levels acutely. Intracellular electrolyte levels should be measured before starting nutrition support, 1 or 2 days after starting support, and at least weekly thereafter. Liver function and coagulation parameters should be evaluated weekly and as needed. Glucose should be measured every 6 hours initially and then as needed; it can be measured as often as every 2 hours when continuous insulin infusions are being used (Fig. 82.1).

COMPLICATIONS OF NUTRITION SUPPORT

Complications of nutrition support include those related to the route of nutrition support and those related to nutrition support in general and are discussed in the following

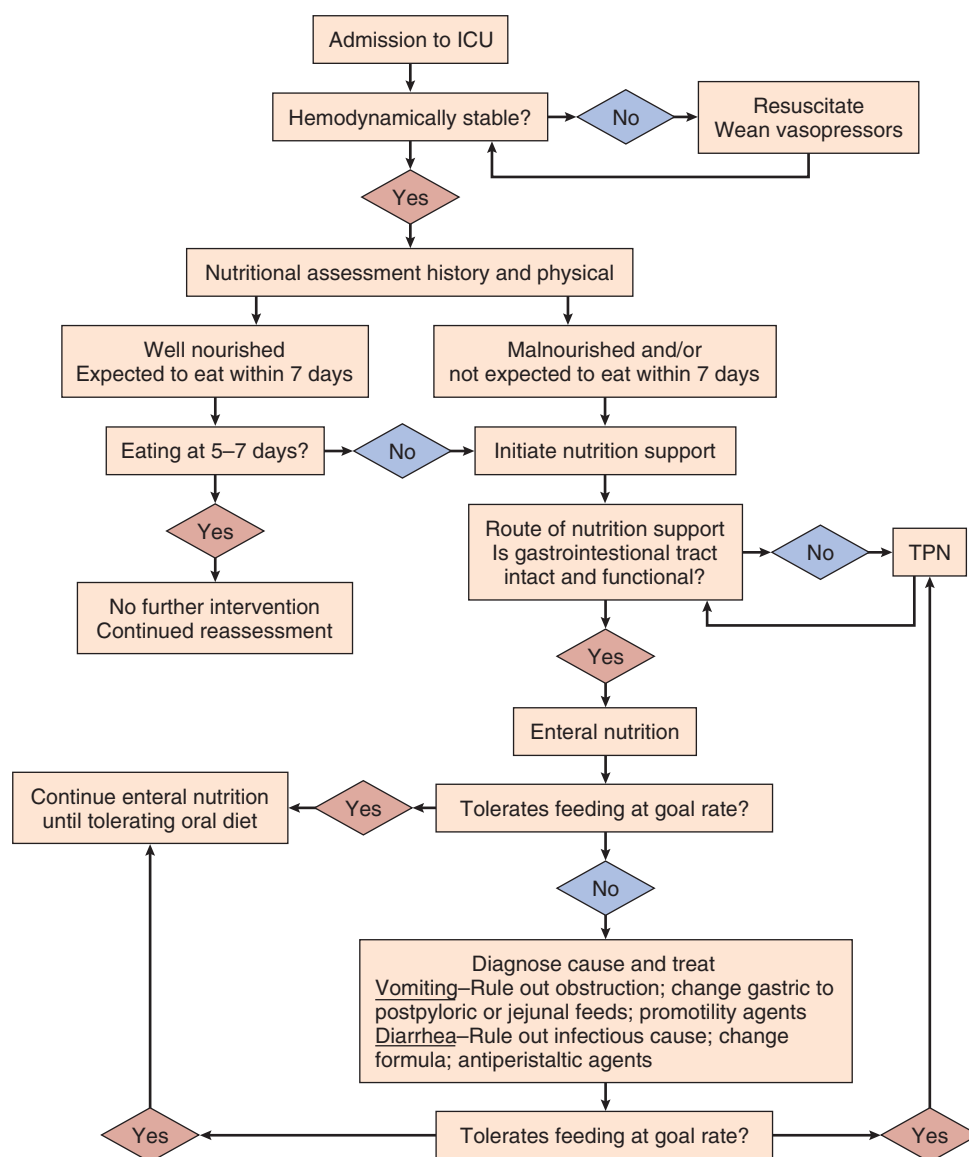

Figure 82.1 Approach to administering nutritional support to a critical care patient. ICU, intensive care unit; TPN, total parenteral nutrition.

paragraphs. Perhaps the most important problem with nutrition support is failure to achieve therapeutic goals. Recommendations for appropriate doses of protein and calories, electrolytes, vitamins, and trace elements are discussed in previous paragraphs.

COMPLICATIONS OF ENTERAL NUTRITION SUPPORT

Complications specific to enteral nutrition support include mechanical or technical complications, gastrointestinal complications, and aspiration pneumonia.

Mechanical and technical complications of enteral nutrition include feeding tube misplacement, gastrointestinal perforation, sinusitis, otitis media, ulceration of the nasal septum, and obstruction of the feeding tube. Proper placement of feeding tubes in the gastrointestinal tract should be confirmed radiographically or with pH testing before feeding is initiated. Auscultatory techniques for confirmation of proper tube placement are unreliable.¹⁵² Nasally placed feeding tubes are a potential cause of sinusitis or otitis media (or both), particularly when stiff, large-bore nasogastric tubes are used as feeding tubes. Soft, small-caliber tubes such as Miller-Frederick or Dobhoff tubes seem to cause sinusitis less frequently. In mechanically ventilated patients, feeding tubes may be placed orally to minimize the incidence of sinusitis.¹⁵³ Perforation of the esophagus or other parts of the gastrointestinal tract is a disastrous complication and seems to occur most frequently in the setting of stricture, obstructing tumor, or abnormal anatomy as a result of surgery. In these situations, tube placement under fluoroscopic guidance or endoscopic tube placement should be considered. Dislodgement of the feeding tube is a frequent and frustrating problem and can be disastrous when the tube dislodged is a recent, surgically placed tube such as a gastrostomy or jejunostomy tube. When a surgically placed tube has been present for longer than 1 to 2 weeks, the stomach or intestine should be adherent to the abdominal wall and the tube can usually be replaced through the existing tract, as long as the tube is replaced within a few hours before the tract begins to close. A radiograph with contrast enhancement should be used to verify replacement of the tube in the appropriate location. Dislodgement of a surgically placed tube within a week of placement can result in peritonitis from spillage of enteral formula or gastrointestinal contents into the abdominal cavity. Care should be taken to properly secure all feeding tubes either with sutures and tape or with commercially available fixation systems, and tubes should be protected with appropriate patient restraints and caregiver attention when the patient is being moved. Feeding tube obstruction occurs most frequently when tubes are not routinely flushed or when crushed medications are delivered through the tubes. Tubes should be flushed every 6 hours and after every medication dose. Numerous techniques have been used to clear obstructed tubes, including flushing with cola, pancreatic enzymes, cranberry juice, and streptokinase, although none is universally successful. Clearing a nasoenteric tube with a stylet or wire carries the risk of perforating the gastrointestinal tract and should be avoided unless done under fluoroscopic guidance to ensure that the stylet remains within the tube lumen.

Gastrointestinal complications such as abdominal distention, nausea, vomiting, diarrhea, and constipation occur in

approximately 60% of critically ill patients receiving nutrition support.¹⁵⁴ Gastrointestinal motility is often decreased in these patients,^{154,155} although gastric stasis and high gastric residual volumes occur more frequently than decreased small intestinal motility does.¹⁵⁵ Potential causes of gastroparesis include increased sympathetic tone, elevated intracranial pressure, opiates, benzodiazepines, dopamine, hyperglycemia, recent abdominal surgery, and pancreatitis. Prokinetic agents such as metoclopramide may restore gastric motility and allow gastric feeding.¹⁵⁶ Postpyloric feeding tube placement will often allow the continuation of enteral nutrition. Advancement of the feeding tube into the proximal jejunum facilitates enteral nutrition in patients with pancreatitis.

Diarrhea occurs in as many as 70% of critically ill patients.¹⁵⁴ Potential causes include antibiotics and other drugs, hyperosmolar formulas, infected solutions, hypoalbuminemia, chronic malnutrition and disuse mucosal atrophy, intolerance to lactose or other nutrients, pancreatic insufficiency, biliary fistula, and short-gut syndrome.

Clostridium difficile overgrowth is perhaps the most serious cause of antibiotic-associated diarrhea, and stool should be assayed for *C. difficile* toxin in every case of persistent diarrhea in the critically ill. *C. difficile* enterocolitis should be treated with appropriate antibiotics. Antibiotics may also cause diarrhea by eliminating the bacteria that ferment dietary fiber into short-chain fatty acids. Short-chain fatty acids are important for maintaining colonic mucosal integrity and enhance water and electrolyte absorption.¹⁵⁷ Enteral formulas should be replaced daily to avoid bacterial contamination of the solution.

A change in formula or more gradual institution of nutrition support can be used to overcome problems caused by nutrient intolerance, disuse atrophy, and short-gut syndrome. Semi-elemental or peptide formulas may reduce diarrhea in patients with mucosal atrophy. H₂ blockers can be used to decrease the contribution of gastric secretions to diarrhea in patients with short-gut syndrome. Drugs with the potential to cause diarrhea should be identified and eliminated if possible. Pancreatic insufficiency should be treated with commercially available pancreatic enzymes. Diarrhea secondary to a biliary fistula may be improved with reinfusion of bile into the intestine distal to the fistula. Once correctable causes of diarrhea have been identified and eliminated, Kaopectate can be given for symptomatic relief. Antiperistaltic agents such as Imodium or opiates should be avoided until infectious causes of diarrhea have been ruled out. Fiber may be used to thicken stool and lessen perineal irritation, but it may be associated with constipation and fecal impaction in critically ill patients. Intractable diarrhea may warrant the discontinuation of enteral nutrition and the initiation of parenteral nutrition.

Aspiration pneumonia is the major infectious complication of enteral nutrition. Bolus feeding carries a higher risk of aspiration than continuous feeding does. Gastric residual volume, which has traditionally been used to assess gastric feeding tolerance, does not appear to correlate with risk for aspiration.¹⁵⁸ Gastric feeding is routinely used in many ICUs, but because a nasogastric tube is one of the leading causes of aspiration, gastric feeding should probably be done with a soft, small-caliber tube designed for feeding. The risk of aspiration associated with gastric feeding may be lower when

done via a percutaneous gastrostomy tube,¹⁵⁸ which avoids compromising the function of the gastroesophageal junction and swallowing mechanics. Multiple studies have compared the risk of aspirating gastric versus postpyloric feedings, but the results have been contradictory.^{71,159,160} In a recent meta-analysis of seven randomized trials, small bowel feeding was associated with a lower risk of aspiration pneumonia than was gastric feeding.¹⁶¹ Nursing protocols for the bedside placement of postpyloric feeding tubes have been developed,^{162,163} although placement under fluoroscopic guidance is more likely to be successful and is cost-effective.¹⁶⁴ The semirecumbent body position has been shown to significantly reduce aspiration pneumonia as compared with the supine body position.¹⁶⁵

COMPLICATIONS OF PARENTERAL NUTRITION SUPPORT

The primary complications of parenteral nutrition include mechanical or technical complications and infectious complications. Mechanical and technical complications are related to central venous catheter placement and include pneumothorax, arterial injury, hemothorax, hydrothorax, cardiac arrhythmia, and cardiac perforation with tamponade. The incidence of severe complications with subclavian vein catheterization is 1% to 3%, with an overall complication rate of 5%.¹⁶⁶ The incidence of complications with jugular venous catheterization ranges from 0.1% to 4.2%.¹⁶⁷ Jugular venous catheterization under ultrasound guidance is increasingly being recommended.¹⁶⁸⁻¹⁷¹ Jugular or subclavian vein thrombosis is a postprocedural complication that is manifested as neck or arm swelling and should be managed by catheter removal and anticoagulation; thrombolytics have also been recommended.¹⁷²

Catheter infection and catheter-associated bloodstream infection are the major infectious complications of parenteral nutrition and occur in 2% to 8% of patients with central venous catheters. The most common infecting organisms are coagulase-negative staphylococci, *Staphylococcus aureus*, and *Candida* species. Infection is more likely when parenteral nutrition is administered through a multi-lumen catheter than through a single-lumen catheter,¹⁷³ although the incidence of infection may be reduced when parenteral nutrition is infused through a dedicated port.¹⁷⁴ Jugular and femoral catheters have higher rates of infection than do subclavian catheters.¹⁷⁵ Dedicated central line care teams and regular dressing change protocols may reduce the incidence of catheter infection.¹⁷⁴ Antibiotic-coated or antibiotic-impregnated catheters are expensive but appear to be effective in reducing catheter-related bloodstream infections.¹⁷⁶ Guidewire exchange is associated with a decreased incidence of technical complications but an increased incidence of catheter infections.¹⁷⁷ Although the possibility of catheter infection increases with time, routine catheter exchange is probably not indicated.¹⁷⁶ Catheters should be replaced, ideally at a fresh site, for obvious site infection, for the evaluation and treatment of fever of unknown origin, and after any positive blood culture. If guidewire exchange is used and the removed catheter proves to be infected, the new catheter often becomes infected during the exchange and should in turn be removed and replaced at a fresh site.

METABOLIC COMPLICATIONS OF NUTRITION SUPPORT

Common metabolic complications of nutrition support include hyperglycemia, hepatobiliary complications, disturbances in water and electrolyte balance, and acid-base abnormalities. Though more common in patients receiving parenteral nutrition, metabolic complications can occur with either form of nutrition support.

Hyperglycemia occurs frequently in critically ill patients receiving nutrition support and is most common in diabetic patients and those with catabolic illness.

Complications related to hyperglycemia include infection, hyperosmolality, and osmotic diuresis. The first step in the control of blood sugar is avoidance of overfeeding, as discussed previously. Insulin, whether by intermittent dosing or continuous infusion, is the mainstay for maintenance of acceptable blood glucose levels. The appropriate glucose level has been the subject of controversy. In a large, prospective, randomized trial in critically ill surgical patients, tight glucose control (80-120 mg/dL) was associated with significantly decreased mortality rate, infection, neuropathy, and renal failure.⁴⁹ In medical ICU patients the same tight glucose control protocol was associated with decreased renal failure, ventilator days, and reduced ICU and hospital length of stay, but not improvements in mortality rate or infection.¹⁷⁸ Subsequently, the NICE-SUGAR trial compared tight glucose control to glucose levels less than 180 mg/dL and demonstrated similar infection and mortality rates and fewer episodes of dangerous hypoglycemia with more liberal glucose control.¹⁷⁹ Currently, most practitioners aim for blood glucose levels below 150 to 180 mg/dL. Symptomatic hypoglycemia has been reported in children after sudden withdrawal of TPN but is rare in adults, and weaning of TPN in adults is not usually necessary.¹⁸⁰

Hepatobiliary complications of nutrition support include hepatic steatosis (fatty infiltration of the liver) and intrahepatic and extrahepatic cholestasis. Progression to chronic liver disease occurs in premature infants¹⁸¹ but is rare in adults. Hepatic steatosis may develop after 7 to 21 days of parenteral nutrition and is characterized initially by elevated transaminases. Usually asymptomatic, fatty infiltration can, in severe cases, be accompanied by hepatomegaly and right upper quadrant abdominal pain. Histologically, mild cases are characterized by periportal fat infiltration and severe cases by centrilobular infiltration. Overfeeding, hyperinsulinemia, essential fatty acid deficiency, and carnitine deficiency may predispose to fatty infiltration. Cholestasis occurs later in the course of parenteral nutrition and is characterized by elevations in bilirubin and alkaline phosphatase. Histologically, periportal or pericentral canalicular bile plugging, bile staining of surrounding hepatocytes, and lymphocytic triaditis characterize cholestasis. Cholelithiasis has been linked to long-term TPN use. Gallstone formation is almost certainly related to the lack of enteral feeding and the resultant lack of neural and hormonal stimulation of gallbladder contraction. Other potential but unproven causes of cholestasis include overfeeding, the production of toxic bile acids by intestinal bacteria, hormones, endotoxin, and taurine deficiency.^{31,182-185} Management of hepatobiliary complications is aimed at prevention. Overfeeding should be avoided. Cyclical TPN and enteral feeding, even if only

partial, may help prevent cholestasis. A trial of oral neomycin and metronidazole may be helpful.¹⁸⁵

Serum electrolyte levels should be monitored and electrolytes added to or eliminated from TPN as indicated, with consideration of excess losses or abnormal accumulation. Hypernatremia or hyponatremia can be managed by increasing or decreasing free water. Particular attention should be paid to the intracellular electrolytes potassium, magnesium, and phosphorus. In malnourished individuals, these electrolytes rapidly move intracellularly when nutrition support is initiated. In what is termed the refeeding syndrome, serum levels of these intracellular electrolytes fall precipitously, with hypophosphatemia resulting in hemolysis, rhabdomyolysis, and heart failure with hypokalemia and hypomagnesemia leading to cardiac arrhythmias.^{186,187} Serum levels of intracellular electrolytes should be corrected before and, in particular, 24 hours after the institution of nutrition support. Abnormally high levels of the intracellular electrolytes are of concern in renal failure and often need to be reduced or eliminated from TPN solutions. Hyperkalemia and hypomagnesemia may lead to weakness and cardiac arrhythmia, and hyperphosphatemia may result in hypotension, hypocalcemia, and metastatic calcification. Hyperphosphatemia is often treated with oral phosphate binders such as calcium carbonate.

Metabolic acidosis related to nutrition support is most commonly due to excess chloride administration and resultant renal bicarbonate losses, but it can also occur as a result of thiamine deficiency with resultant lactic acidosis.^{188,189}

KEY POINTS

- Malnutrition is a significant contributor to morbidity and mortality rates in critically ill patients.
- Distinguishing stress metabolism from starvation metabolism is critical to the provision of appropriate nutrition support.
- Critically ill patients may require more energy but are less able to tolerate glucose than starved patients are and require a significant portion of calories as fat.
- Critically ill patients require increased protein to achieve nitrogen balance.
- Enteral nutrition is less costly and more physiologic; is associated with fewer metabolic disturbances; and may be associated with fewer infections than

KEY POINTS (Continued)

parenteral nutrition is and thus remains the preferred route for nutrition support.

- Parenteral nutrition is acceptable when enteral nutrition cannot be used, particularly if blood glucose is tightly controlled.
- Nutrition support should be closely monitored to avoid complications.

ULTRASONOGRAPHY

VASCULAR ACCESS

Ultrasonography has become an invaluable tool in the management of critically ill patients. Its safety and portability allow for use at the bedside to provide rapid, detailed information regarding the cardiovascular system and the function and anatomy of certain internal organs. A new generation of portable, battery-powered, inexpensive, hand-carried ultrasound devices has recently become available. The true portability, ease of use, and low cost make these devices ideally suited for use by the intensivist. The safety and utility of bedside ultrasonography performed by adequately trained intensivists has now been well demonstrated. All intensivists should be trained to perform “focused” ultrasound examinations that answer specific questions applicable to the management of critically ill and injured patients. It is important to emphasize that ultrasonography performed by the intensivist is an extension of the patient’s evaluation rather than being a discrete imaging procedure. Furthermore, it is performed by the clinician caring for the patient rather than a subspecialty consultant, and it is contemporaneous with the intensivist’s evaluation rather than being temporally distinct. This chapter reviews the indications and techniques for extracardiac ultrasonography in the intensive care unit (ICU).

LUNG ULTRASONOGRAPHY

Lung ultrasonography is a valuable tool in the assessment of critically ill patients. The diagnostic accuracy of using ultrasound in the lung to establish the presence of

pneumothorax, pleural effusion, lung consolidation, and alveolar-interstitial syndrome has been well established.¹ Lung ultrasonography can be rapidly performed at the bedside and has been shown to significantly aid in the management of critical patients.² Lung computed tomography (CT) remains the gold standard for thoracic imaging in the critical care setting, despite its major drawbacks (radiation, cost, transportation), even though portable chest radiography is the most common diagnostic imaging modality.²⁻⁴ Although portable chest radiographs are routinely performed in the ICU, multiple studies have shown limited diagnostic accuracy, with the elimination of routine chest radiographs having no adverse effect on length of stay, readmission, and mortality rates.⁵⁻⁷ Routine use of bedside lung ultrasound in the ICU has been shown to significantly reduce the number of both chest radiographs and CT scans obtained.⁸

TECHNIQUE AND EQUIPMENT

In normal lung, ultrasound waves are reflected off gas-filled structures, limiting the visualization of lung structures beyond the pleura.¹ The diagnosis of lung disease by ultrasound largely relies on the detection of ultrasound artifacts. To examine the thorax, a high-frequency linear transducer (5-12 MHz) is best used to visualize the relatively superficial pleural line. Lower frequency microconvex and convex transducers (2-5 MHz) can be used to scan the deeper lung parenchyma.⁹ Supine positioning is most commonly utilized in the ICU, and lateral decubitus positioning may assist in the visualization of the dorsal aspects of the lower lobes. To

Figure 83.1 The pleural line appears as a hyperechoic horizontal line (straight arrow) approximately 0.5 cm deep to the anterior border of the ribs (curved arrow).

perform lung ultrasonography the transducer should be placed in a longitudinal axis, between two ribs. In this view the pleural interface can be seen as a hyperechoic horizontal line approximately 0.5 cm deep, relative to the anterior border of the ribs^{1,10} (Fig. 83.1). This image of the ribs and pleural line is the basic landmark in lung sonography and is often referred to as the *bat sign*.^{10,11}

PNEUMOTHORAX

Pneumothorax, defined as a collection of air between the visceral and parietal pleural layers, has a frequency of approximately 6% in the ICU setting.¹² Although screening for pneumothorax with supine anteroposterior (AP) chest radiography is still common in the critical care setting, sensitivities for the diagnosis of pneumothorax average 50%.¹³ The sensitivity for diagnosis of pneumothorax by lung ultrasound has been shown to be greater than 95% in multiple large prospective studies.¹⁴ Moreover, lung ultrasound for pneumothorax can be completed in an average of 2 to 3 minutes, significantly faster than obtaining a portable chest radiograph or transport to CT scan.¹⁵ The examination should begin with the transducer placed longitudinally at the midclavicular line at the level of the second to third intercostal space. Sequential movement of the transducer inferior and lateral across multiple rib interspaces will allow for a comprehensive examination of the pleura.⁹ This approach should then be repeated on the opposite hemithorax.

Focusing on the pleural line in real time, a sliding type of motion of the visceral and parietal pleura can be observed. This dynamic motion is termed *lung sliding*, and can be seen in normal lung ultrasound (Video 83.1). In the presence of a pneumothorax, air is trapped between the visceral and parietal pleural layers and the dynamic motion of lung sliding will not be detected (Video 83.2). The presence of lung sliding alone has a 100% negative predictive value in the diagnosis of pneumothorax.¹⁶ However, the absence of lung sliding does not rule in the diagnosis of pneumothorax. A number of conditions can result in the absence of

Figure 83.2 M-mode imaging of normal lung tissue, demonstrating the “seashore sign.” The linear pattern superior to the pleural line (arrow) represents the motionless chest wall, and the granular pattern below the pleural line represents normal lung tissue.

Figure 83.3 M-mode imaging of a pneumothorax, demonstrating the “stratosphere sign.” Exclusively horizontal linear lines are displayed.

lung sliding such as massive atelectasis, acute respiratory distress syndrome (ARDS), pleural adhesions, and severe fibrosis.^{9,10} M-mode and power Doppler may be useful when lung sliding is difficult to visualize on real-time B-mode imaging. M-mode analysis of normal lung tissue displays the “seashore sign,” a characteristic linear wave pattern representing the motionless chest wall, and below the pleural line a granular pattern represents normal lung motion¹⁷ (Fig. 83.2). M-mode analysis of a pneumothorax demonstrates the “stratosphere sign,” a characteristic appearance of exclusively linear lines¹⁰ (Fig. 83.3). Power Doppler will depict motion along the pleural interface, corresponding to normal lung sliding (Fig. 83.4). In the presence of a pneumothorax, no Doppler signal will be detected along the pleural surface. The visualization of the lung point may also be used in the diagnosis of pneumothorax, having a specificity of 100%. The lung point represents the area on the chest wall where normal lung sliding is again appreciated,

Figure 83.4 Power Doppler of normal lung tissue, which demonstrates the presence of a Doppler signal along the pleural interface.

Figure 83.6 A lines, reverberation artifacts, represented as horizontal lines (arrows) parallel to the pleural line. A lines are found in a repetitive equidistant pattern below the pleural line.

Figure 83.5 M-mode ultrasound imaging of the lung point, correlating with the lateral edge of the pneumothorax.

Figure 83.7 B lines, or comet tails, are vertical linear artifacts that extend the entire length of screen.

corresponding to the lateral edge of the pneumothorax (Fig. 83.5). This confirms the absence of visualization of lung sliding was not due to technical errors in lung ultrasound, but rather the presence of pneumothorax.¹⁰

Two linear artifacts arising from the pleural line are key to the evaluation of pneumothorax by lung ultrasound, A and B lines. A lines are a reverberation artifact of the parietal pleura, represented as horizontal lines in a repetitive pattern (Fig. 83.6). B lines, or comet tails, are described as vertical lines extending the length of the screen, which erase A lines and move with lung sliding¹² (Fig. 83.7). In lung ultrasound, the appreciation of only one B line indicates normal apposition of the parietal and visceral pleura and rules out pneumothorax at that location.⁹ Because A lines arise from the parietal pleura, their presence can be appreciated in both normal lung and pneumothorax. The absence of lung sliding with the presence of A lines has a sensitivity of 95% and specificity of 94% in the diagnosis of pneumothorax.¹²

LUNG CONSOLIDATION

Alveolar consolidation, seen in pulmonary edema, bronchopneumonia, lung contusion, and lobar atelectasis, results in the loss of lung aeration replaced by fluid, allowing for ultrasound transmission and imaging.¹ As the ratio of lung tissue to air increases, lung hepatization appears on ultrasound imaging, with the lung parenchyma taking a hepatic tissue-like appearance³ (Fig. 83.8). Consolidated lung adjacent to the pleura will permit the transmission of ultrasound waves. A prospective clinical study in a medical ICU setting showed that 98% of alveolar consolidations abutted the pleura, allowing for ultrasound assessment. The deep border of alveolar consolidations will typically have an irregular appearance, sometimes referred to as the shred sign, unless the entire lobe is involved.¹⁰ Using CT as the gold standard, ultrasound has a 90% sensitivity and 98% specificity in the diagnosis of alveolar consolidation.¹⁸ Air bronchograms can be visualized within consolidated lung as bright highly

Figure 83.8 Hepatization of lung tissue seen with consolidation.

reflective echogenic lines.²¹ Dynamic air bronchograms move centrifugally during inspiration and can typically be seen in pneumonia, as opposed to static air bronchograms of atelectasis.¹⁹

ALVEOLAR-INTERSTITIAL SYNDROME

Alveolar-Interstitial syndrome is a common entity in the ICU, caused acutely by a variety of conditions, including ARDS, acute pulmonary edema, and interstitial pneumonia.²⁰ Interstitial edema precedes alveolar edema and may be difficult to discern on chest radiograph. Interstitial edema can be visualized on lung ultrasound by demonstrating three or more B lines located between two ribs, defined as lung rockets²¹ (Fig. 83.9 and Video 83.3). B lines 7 mm apart correspond to thickened interlobular septa and extravascular lung volume, but B lines 3 mm apart or less correspond to alveolar edema and a ground-glass appearance of the lung.²² In an acutely dyspneic patient, the detection of lung rockets allows the intensivist to immediately differentiate acute pulmonary edema from chronic obstructive pulmonary disease (COPD). Lung rockets are also unusual in the presence of pulmonary embolism.¹⁰ It is important to remember that B lines may be isolated or confined laterally in the last intercostal space in normal healthy lung.²³

PLEURAL EFFUSION

The prevalence of pleural effusion is approximately 60% in the ICU setting.²⁴ Pleural effusion may arise from a variety of conditions, most commonly heart failure, atelectasis, pneumonia, and volume overload. Portable supine chest radiography has poor sensitivity and specificity in the diagnosis of a pleural effusion, but lung ultrasound outperforms both chest radiography and clinical examination. Lung ultrasound can help differentiate pleural effusions from infiltrate or atelectasis, with a sensitivity of 92% and specificity of 93%.²² Pleural effusions appear as an anechoic area in dependent lung regions (Figs. 83.10 and 83.11). Transudative fluid appears echo-free, and exudative fluid may contain small echogenic debris. In intercostal imaging, pleural effusions will be bordered laterally by rib shadows, superiorly by

Figure 83.9 Multiple lung rockets visualized as hyperechoic vertical lines extending from the pleural line to the entire length of the image.

Figure 83.10 A right-sided pleural effusion (star) located cranially to the liver (red arrow) and seen surrounding lung tissue (blue arrow).

the parietal pleural line, and inferiorly by the lung line. M-mode analysis demonstrates a decrease in the interpleural distance with inspiration, known as the sinusoid sign¹⁰ (Fig. 83.12). Lung ultrasound can also help estimate volume of pleural fluid. An anteroposterior diameter greater than 5 cm measured at the lung base or fifth intercostal space predicts a pleural effusion fluid volume of greater than 500 mL.²⁵

THORACENTESIS

The utilization of ultrasound to determine needle placement in thoracentesis has been shown in multiple studies to

Figure 83.11 Left-sided pleural effusion (star).

Figure 83.13 Ascites visualized in the left lower quadrant, with loops of bowel demonstrated floating in ascitic fluid (star).

Figure 83.12 M-mode lung imaging demonstrating the sinusoidal sign of pleural effusion.

significantly decrease complication rates, especially that of pneumothorax.²⁶⁻²⁸ Localization of fluid above the diaphragm should be the first objective, avoiding mistaking peritoneal for pleural fluid.²⁸ Once pleural fluid is visualized, the transducer should be moved one interspace above and below to evaluate the extent of the effusion.²⁹ The chest should be scanned in both the longitudinal and cross-sectional plane and the positions of the heart, diaphragm, and liver/spleen determined. Next, an interpleural measurement (parietal pleura to visceral pleura) of at least 1.5 cm during inspiration should be obtained to allow for safe needle puncture. The potential site of needle puncture should be observed throughout the entire respiratory cycle to evaluate for the appearance of lung, heart, liver, or spleen in the projected needle path.²⁸ After a safe site has been identified, the skin should be marked and disinfected. It is essential the patient remain in the same position as when the ultrasonography was performed.³⁰ Real-time guidance is not necessary for needle puncture, but needle insertion should occur within minutes of ultrasound marking.³¹

ABDOMINAL ULTRASONOGRAPHY

PARACENTESIS

Paracentesis is a commonly performed procedure in the critical care setting. Bedside ultrasonography prior to every paracentesis improves both the safety and efficacy of this procedure.^{32,33} An emergency department study comparing ultrasound-assisted paracentesis versus traditional blind technique showed a 95% success rate with ultrasound guidance versus only 61% with the traditional technique. Moreover, 25% of patients randomized to the ultrasound-assisted technique completely avoided the procedure due to either the absence of ascitic fluid or too little ascitic fluid for aspiration. Two more patients in this group did not receive paracentesis after performance of bedside ultrasound, which revealed a large cystic mass in the left lower quadrant of one patient and a ventral hernia in the other, both of which were mistaken for ascitic fluid and in which performance of paracentesis would have been potentially disastrous.³³

A low-frequency curved array transducer is preferred. As with the traditional blind technique, the urinary bladder should be decompressed and the patient should be lying supine. Ascites will appear as anechoic fluid within the peritoneal cavity and often loops of bowel will be seen floating within this fluid (Fig. 83.13). Ultrasonographic guidance assists in determining the amount and location of ascitic fluid while mapping the most appropriate point of entry and puncture angle. Measurement of abdominal wall thickness can be performed to determine puncture depth. The location of the urinary bladder, bowel, solid organs, and abdominal wall vasculature may all be visualized for avoidance. Such intra-abdominal structures should be visualized in real time throughout the respiratory cycle to ensure they do not cross into the anticipated needle path. Once an appropriate fluid pocket has been determined, it should be visualized in at least two perpendicular planes to ensure avoidance of critical structures. An estimate of the abdominal wall thickness should be made, as well as the depth of the fluid pocket until critical structures such as bowel or

bladder are encountered. Once the site has been mapped and marked, needle puncture may occur. Paracentesis involving small volumes may be better performed with real-time ultrasound guidance, allowing direct visualization of the needle entering the peritoneal space. Most larger volume paracentesis may be performed with mapping of the puncture site and needle with ultrasound guidance, although the actual needle puncture occurs without real-time ultrasound visualization.

THE “FAST” EXAMINATION

The focused assessment with sonography for trauma (FAST) examination has been used by trauma surgeons for decades to identify intra-abdominal fluid.³⁴ The identification of free fluid—hemoperitoneum or ascites—in the abdomen may also be essential in the critical care setting. Localization of ascitic fluid for paracentesis and hemoperitoneum in the setting of persistent or undifferentiated hypotension may prove beneficial in the ICU.

The FAST examination is based on the principle that in a supine patient, free intraperitoneal fluid will accumulate in the most dependent regions of the peritoneal cavity. The most dependent areas in the male and female are the rectovesical pouch and pouch of Douglas, respectively. Free intraperitoneal fluid in the right upper quadrant will accumulate in Morison’s pouch, but fluid in the left upper quadrant will accumulate in the left subphrenic space and splenorenal recess. A prospective study that compared diagnostic peritoneal lavage, CT scanning, and abdominal ultrasound showed an accuracy of 93% for abdominal ultrasound.³⁵ Moreover, the time required to perform such an examination averages less than 3 minutes.³⁶

The FAST examination is performed with either the low-frequency phased array or curvilinear probe. The basic views of the intra-abdominal assessment of the FAST examination include Morison’s pouch, left lateral longitudinal, and pelvic views.³⁴ Starting with Morison’s pouch, in the supine patient, the probe is placed in the right midaxillary line at the level of the lower ribs. The right hemidiaphragm, liver, and right kidney should be visualized (Figs. 83.14 and 83.15). Free fluid in Morison’s pouch will be appreciated as an anechoic area (Fig. 83.16). Massive hemoperitoneum may be rapidly diagnosed with this single view with a sensitivity of 82% and accuracy of 91%.³⁷ Next, the left side is evaluated by placing the probe in the posterior axillary line at the level of the lower ribs. The left hemidiaphragm, spleen, and left kidney can all be identified from this view (Fig. 83.17). Free fluid can be appreciated as an anechoic stripe in the subphrenic space and splenorenal recess. Lastly, the pelvic view is obtained by placing the probe in a midline transverse position just above the pubic symphysis. A fluid-filled urinary bladder appears as well-circumscribed anechoic fluid with posterior acoustic enhancement (Fig. 83.18). A longitudinal view can also be obtained by rotating the probe 90 degrees clockwise. In female patients, the uterus may be seen posterior to the urinary bladder and free fluid may be appreciated in the pouch of Douglas. In male patients, the prostate may be seen posterior to the urinary bladder and free fluid may be appreciated in the rectovesical pouch. The FAST examination does have its limitations, with the patient’s body habitus greatly affecting the quality

Figure 83.14 FAST (focused assessment with sonography for trauma) imaging of Morison’s pouch, demonstrating the interface (arrow) between the right kidney and liver.

Figure 83.18 A fluid-filled urinary bladder, visualized as a well-circumscribed anechoic structure.

of the images obtained. Moreover, ultrasound is capable of identifying free fluid in the abdomen, but it cannot accurately distinguish ascites from hemoperitoneum. Last, ultrasound is not sensitive for the identification of free fluid in the retroperitoneum.

ABDOMINAL AORTA

The abdominal aorta may also be imaged by ultrasonography to diagnose both an abdominal aortic aneurysm (AAA) and dissection. Unexplained hypotension, syncope, dizziness, or cardiac arrest may be caused by a ruptured aneurysm. The prevalence of AAAs is relatively common, ranging from 2% to 5% in adults over the age of 50.³⁸⁻⁴² Bedside ultrasonography in the detection of AAA is highly sensitive, specific, and accurate.^{43,44}

The abdominal aorta extends from the level of the diaphragm at approximately the twelfth thoracic vertebra down to its bifurcation into the common iliac arteries around the level of the umbilicus. The aorta can be best visualized with

Figure 83.19 Transverse view of the abdominal aorta, which lies anteriorly to the hyperechoic vertebral body (arrow) with posterior shadowing. Wall measurements should be obtained measuring the outer to outer wall.

Figure 83.20 A transverse view of the aorta (red arrow), with the inferior vena cava visualized to the right (blue arrow). The superior mesenteric artery is seen in transverse view anterior to the aorta with the splenic vein coursing horizontally above the superior mesenteric artery (green arrow).

a curvilinear probe, either longitudinal or transverse. Generally the patient will be positioned supine, but if obesity or bowel gas obstructs the images, the patient may be moved into a decubitus position. Starting transverse in the epigastrium with the probe marker to the patient's right, the abdominal aorta is seen lying superiorly and slightly to the left of the patient's spine. The vertebral body appears as a bright hyperechoic structure with posterior shadowing (Fig. 83.19). The most proximal branch seen on ultrasound is the celiac trunk branching off anteriorly, followed by the superior mesenteric artery (SMA) approximately 1 to 2 cm distally (Video 83.4). Continuing caudally, the renal arteries can be appreciated branching off laterally just distal to the SMA. The inferior mesenteric artery and paired gonadal arteries may be difficult to image on bedside ultrasonography. The inferior vena cava (IVC) should also be appreciated coursing to the right of the aorta (Fig. 83.20). Turning

Figure 83.21 A longitudinal view of the abdominal aorta.

Figure 83.23 An echogenic linear flap, representing an aortic dissection (arrow), can be visualized in the abdominal aorta.

Figure 83.22 Abdominal aortic aneurysm measured in the anteroposterior diameter, outer wall to outer wall.

the probe 90 degrees clockwise allows the aorta to be viewed in the longitudinal plane (Fig. 83.21). Often, the celiac trunk and SMA can be visualized branching from the anterior aspect of the aorta (see Video 83.4). Tilting the probe slightly to the patient's right will place the IVC in view. Care must be taken not to confuse the IVC for the aorta.

Measurements of the abdominal aorta should be taken in the anteroposterior diameter in the transverse orientation. The calipers should be placed on the outer wall to outer wall. Measurements in the longitudinal orientation may lead to underestimation if the image plane is obtained tangentially. Diameters greater than 3 cm are considered to be abnormal (Fig. 83.22). Although the large majority of dissections start in the thoracic aorta, those that extend to the abdominal aorta can be appreciated on abdominal ultrasonography. An echogenic linear flap can be visualized in the abdominal aorta (Fig. 83.23). If appreciated, further imaging modalities should be performed to assess the thoracic aorta.

RENAL ULTRASONOGRAPHY

Acute renal failure is a common diagnosis encountered in those who are critically ill. In the critical care setting, acute renal failure has a mortality rate of 20% to 30%, which increases with each additional organ system involved.⁴⁵ Evaluation of acute renal failure begins with determining if the cause is prerenal, postrenal, or intrinsic. Bedside ultrasound can quickly determine if postrenal causes are present, demonstrating a large distended urinary bladder or hydronephrosis.⁴⁶⁻⁴⁸

Imaging of the urinary bladder is performed with a curvilinear probe, with the probe marker toward the patient's right in transverse orientation, and with the probe marker toward the patient's head in longitudinal orientation. The probe should be placed just superior to the pubic symphysis. A quick visual assessment of urinary bladder size can be determined. Bladder volume can also be estimated by using the formula width \times depth \times length \times 0.75. A postvoid residual volume greater than 100 mL is consistent with urinary retention.⁴⁹ If no ureteral obstruction is present, one can appreciate ureteral flow jets visualized intermittently near the trigone of the urinary bladder. This intermittent flow of urine from the ureter into the urinary bladder is best visualized with the use of color Doppler (Fig. 83.24). If urinary retention is present, the kidneys should next be evaluated for the presence of hydronephrosis. Studies have shown that bedside sonographic evidence of hydronephrosis correlates well with findings on intravenous pyelogram and CT scanning.^{37,50} On ultrasound imaging, the kidney parenchyma appears slightly hypoechoic compared to the adjacent liver or spleen. The renal sinus typically appears hyperechoic owing to its high fat content. The collecting system is generally not well visualized with ultrasound unless some degree of hydronephrosis is present.⁵¹

Ultrasonographically, hydronephrosis is visualized as dilation of the collecting system, which appears dark and anechoic. It can be further classified as mild, moderate, or severe. As the severity worsens, the dilation of the renal pelvis increases, the individual calyces become less distinct,

Figure 83.24 A ureteral jet visualized with color Doppler, representing the intermittent flow of urine from the ureter into the urinary bladder. The color box is placed near the urinary trigone when attempting to visualize a ureteral jet.

Figure 83.25 Moderate right-sided hydronephrosis, with dilation of the collecting system (star).

and thinning of the renal cortex can be appreciated⁵² (Fig. 83.25). Imaging of the right kidney begins with the probe placed in the anterior axillary line, at the subcostal margin. The patient may be lying supine or in the left lateral decubitus position. Once the kidney is identified, slight tilting or sweeping of the probe medially and laterally should be performed to visualize the kidney in its entire longitudinal axis. Turning the probe horizontally to obtain transverse views, sweeping and tilting superiorly and inferiorly, should then be performed. Similarly, when imaging the left kidney, the patient should be placed in either a supine or right lateral decubitus position. The probe should be placed in the posterior axillary line at the subcostal margin and both subcostal and intercostal images may be obtained. Again the probe should be swept or tilted throughout the entire longitudinal axis and then turned 90 degrees to obtain transverse imaging. Normal kidneys measure approximately 9 to 12 cm in length and 4 to 5 cm in width.⁵³ Typically, small, atrophic, and hyperechoic kidneys are indicative of chronic renal

failure. Enlarged kidneys often suggest an acute process, such as infection, renal vein thrombosis, and rejection.⁵⁴

DEEP VEIN THROMBOSIS ULTRASONOGRAPHY

Venous thromboembolic disease is a common entity encountered in the critical care setting. Despite prophylaxis in the critically ill, the incidence of deep vein thrombosis (DVT) remains around 10% in such populations.⁵⁵ Critically ill patients are susceptible to the development of venous thromboembolism from an increased prevalence of risk factors such as immobility, indwelling central venous catheters, cardiac failure, dehydration, and inflammatory states.^{55,56} Many studies have shown that an abbreviated physician-performed bedside compression ultrasound scan may be highly accurate in the diagnosis of proximal lower extremity DVT.⁵⁷⁻⁶⁰ A two-point compression study performed in the emergency department using portable ultrasonography showed a 100% sensitivity and 99% specificity in the diagnosis of proximal lower extremity DVT when compared to lower extremity duplex ultrasonography performed in a radiology department.⁵⁸ The efficiency of physician-performed bedside ultrasound is a great advantage in the critical care setting. The average time for completion of bedside DVT ultrasound was 3.5 minutes, compared to 37 minutes, the average time for completion of formal venous ultrasonography.⁵⁷ This latter time does not take into account transport of critically ill patients to the radiology department or the possibility that the test may be delayed until an ultrasonography technician is available.

The examination for lower extremity DVT is performed with a high-frequency linear transducer. Images can be obtained with the patient supine, the leg externally rotated, and the knee slightly bent. Veins are best visualized at maximal distention, which is achieved by placing the bed in reverse Trendelenburg positioning at 30 to 45 degrees so that pooling of the venous vasculature occurs, enhancing visualization. The examination begins with visualization of the common femoral vein just beneath the inguinal ligament (Fig. 83.26). In most instances the vein will be easily distinguished from the artery; however, color or pulse wave Doppler may be used to help differentiate the vessels. With color Doppler, arterial flow will appear more pulsatile. In pulse wave Doppler, an arterial waveform will show rapid acceleration and deceleration, and a venous waveform will show continuous flow even during diastole. Once the common femoral vein is identified proximally, downward pressure should be applied to the transducer and the vein should collapse completely (Fig. 83.27). Concern for venous thromboembolism occurs if enough pressure is applied to the transducer to cause deformation of the artery without complete collapse of the vein (Fig. 83.28). The transducer should then be moved approximately 1 cm distally with sequential compression until the common femoral vein is seen branching into the superficial and deep branches. Imaging and compression should continue for 1 to 2 cm beyond this point.

The examination then moves to the popliteal region, where the probe is placed in the popliteal fossa. Identification of the popliteal artery and vein should occur with

Figure 83.26 Ultrasound examination of the common femoral artery (blue arrow) and vein (red arrow).

Figure 83.27 The common femoral vein visualized without probe pressure (blue arrow). With gentle pressure placed on the probe, the common femoral vein completely collapses (red arrow).

complete compression of the popliteal vein. Be aware that the popliteal vein may be duplicated and both veins must collapse on examination. Again, sequential compression at approximately 1-cm intervals should occur while moving distally to the trifurcation of the popliteal vein. Proximal DVTs are those located at or above the popliteal vein and imaging of the calf veins is generally not performed in bedside ultrasonography for DVT. While imaging the deep veins of the lower extremity, thrombus may be visualized as echogenic material within the lumen of the vessels under examination. Often this depends both on the age of the thrombus and the quality of the images. Remember, an acute thrombus may not be directly visualized within the lumen because it likely has the same echogenicity as blood.⁵⁶ Lastly, upper extremity DVT accounts for approximately 18% of all venous thromboembolic disease.⁶¹ Bedside ultrasonography for the diagnosis of upper extremity DVT is possible but is technically more involved than for lower extremity imaging. The examination will not be discussed further in this chapter.

Figure 83.28 The common femoral vein visualized without probe pressure (blue arrow). With the addition of gentle probe pressure, the common femoral vein does not collapse (red arrow). Moreover, echogenic material can be observed inside the lumen of the common femoral vein, representing thrombus.

VASCULAR ACCESS

Central venous catheterization is a common procedure performed in the ICU, with an estimated 5 million central venous lines placed annually in the United States. Central venous access is often essential for volume resuscitation, hemodynamic monitoring, vasopressor therapy, and frequent blood sampling.⁶² Traditionally, central venous catheterization was performed with a blind technique, using external anatomic landmarks to assist in vessel location.

Use of Doppler ultrasound for localization of the internal jugular vein in central venous catheterization has been described since 1984.⁶³ A meta-analysis evaluating both real-time or Doppler assisted ultrasound guidance in central venous cannulation demonstrated that ultrasound guidance significantly decreased catheter placement failure by 64% when compared to standard landmark techniques. Likewise, the use of ultrasound decreased complications during placement by 78% and decreased the need for multiple needle passes by 40%.⁶² Common complications of central venous cannulation include carotid artery puncture, neck or mediastinal hematomas, brachial plexus injury, and pneumothorax.⁶⁴ Studies evaluating the anatomic variation of the internal jugular vein using two-dimensional ultrasound show that the position of the internal jugular vein was outside the path predicted by external landmark techniques in 5.5% to 12% of cases.^{65,66}

Veins and arteries are easily identified with ultrasound. A 7.5- to 10-MHz linear array transducer should be used for vessel imaging. Blood vessels appear black, or anechoic, owing to complete transmission of ultrasound waves. Arteries are pulsatile and difficult to compress with the ultrasound transducer. Veins are nonpulsatile, are easily compressed with the ultrasound transducer, and will distend when the patient performs a Valsalva maneuver or is placed in the Trendelenburg position.⁶⁷ The vessel can be viewed in either the longitudinal/long-axis approach or transverse/short-axis approach (Figs. 83.29 to 83.31). The transverse,

Figure 83.29 Visualization of the internal jugular vein (red arrow) slightly lateral to the carotid artery (blue arrow). Notice the carotid is circular, although the internal jugular vein appears slightly flattened.

Figure 83.31 Longitudinal imaging of the internal jugular vein (blue star) lying anterior to the common carotid artery (red star).

Figure 83.30 Visualization of the internal jugular vein (red arrow) lying directly over the common carotid artery (blue arrow).

Figure 83.32 Longitudinal vascular orientation, which visualizes the needle (arrow) traversing through the superficial soft tissue and puncturing the deeper anterior vessel wall.

short-axis approach has been shown to be easier for novices to learn.⁶⁸ In the short-axis view, however, the tip of the needle must remain in axis with the ultrasound beam in order to be visualized.

The dynamic approach uses direct ultrasound guidance to visualize the needle puncturing the vessel in real time (Fig. 83.32). The patient should be prepped in the usual sterile fashion, and the ultrasound transducer should be placed into a sterile transducer cover, and sterile ultrasound gel should be used throughout the procedure. Ultrasound gel must be placed both inside the sterile cover contacting the probe and outside the sterile cover contacting the patient's skin. Holding the transducer in the nondominant hand and the introducer needle in the dominant hand, the operator can visualize the needle tip puncturing the appropriate vessel. The transducer should then be placed down while the guidewire is inserted. Once the guidewire is

placed, ultrasound should be used to confirm placement of the wire in the appropriate vessel to avoid inadvertently dilating an artery or soft tissue structures. Needle guidance devices, which attach onto the ultrasound transducer, can be used in the dynamic approach to control needle trajectory.⁶⁹ This choice is a technical consideration and is based on operator preference. A static approach may also be used in which the vessel is located using ultrasound guidance to confirm predicted landmark anatomy. The ultrasound transducer is then put down, the patient is prepped in the usual fashion, and the vessel is cannulated without real-time ultrasound imaging. Ultrasound guidance may also be used for arterial or peripheral vein puncture. Arterial puncture of the femoral, axillary, or radial arteries is commonly performed with ultrasound guidance. Similarly, venous access of the deeper cephalic, basilic, and brachial veins can be obtained using ultrasound to assist in visualization.⁶⁹

KEY POINTS

- The true portability, ease of use, and low cost make current ultrasound devices ideally suited for use by the intensivist.
- In the presence of a pneumothorax, air is trapped between the visceral and parietal pleural layers and the dynamic motion of lung sliding will not be detected.
- Consolidated lung adjacent to the pleura will permit the transmission of ultrasound waves.
- In an acutely dyspneic patient, the detection of lung rockets allows the intensivist to immediately differentiate acute pulmonary edema from COPD.
- Lung ultrasound can help differentiate pleural effusions from infiltrate or atelectasis, with a sensitivity of 92% and specificity of 93%.
- With the use of ultrasound during paracentesis the location of the urinary bladder, bowel, solid organs, and abdominal wall vasculature may all be visualized for avoidance.
- The abdominal aorta may be imaged by ultrasonography to diagnose both an AAA and dissection.
- Bedside ultrasound can quickly determine if postrenal causes of acute renal insufficiency are present, demonstrating a large distended urinary bladder or hydronephrosis.
- Studies have shown that an abbreviated physician-performed bedside compression ultrasound scan is very accurate in the diagnosis of proximal lower extremity DVT.
- The use of ultrasound has been shown to decrease complications during placement of internal jugular catheters by 78% and decrease the need for multiple needle passes by 40%.
